I find it impossible to interpret my own experiments in terms of much of the recent American research on rickets in rats, where the standard rickets-producing diet is deficient in both the fat-soluble vitamin and phosphorus.⁴ It is true that meat has some antirachitic action, and this may be related to its high phosphorus content, but its effect in any case is small. Again, separated milk powder when given in large quantities, with the cereal element of the diet low, has an antirachitic action. This may be related to its high phosphorus content. As mentioned above, however, there is undoubtedly some fat-soluble vitamin left in separated milk, and its action on calcification becomes apparent when large quantities are ingested. When, however, the rickets-producing effect of the cereals is considered, it is manifest that phosphorus is of secondary consideration, because oatmeal, which has the strongest effect in inducing rickets of all

the cereals so far examined, has also the highest phosphorus content, the P_2O_5 in oatmeal, flour, and rice being of the order 1.25 per cent., 0.25 per cent., and 0.2 per cent., respectively.

(b) The Effect of Cereals.

Whereas the fat-soluble vitamin working in conjunction with calcium and phosphorus ensures the calcification of bone, other elements in the diet have an influence in promoting the laying down of new bony basis without at the same time ensuring its calcification. Whether they actually inhibit calcification or are simply indifferent to this change is not certain, but in either case they have a definite rickets-producing effect as opposed to the calcifying or antirachitic action of the vitamin substances discussed. The worst offenders are the cereal and carbohydrate elements of the diet. This action of food was suggested by Cheadle⁸ and has been long dismissed by clinicians, but, as far as I know, the fact has never been proved until recently, and there was no experimental evidence in support of it.

I have shown that, when puppies eat diets which are complete except for a deficiency of fat-soluble vitamin, the severity of the rickets produced depends on the amount of cereal eaten if all other conditions are constant. If, for instance, a puppy A eats 2x bread as compared with B eating x bread, then, all other conditions being constant, A will develop worse rickets than B. I thought at the time, and I attempted to prove, that the carbohydrate moiety of the cereal was the essential element responsible for the action. These latter experiments were not very successful because of the difficulty in getting young puppies to eat diets deficient in fat-soluble A and rich in pure carbohydrate such as starch, cane-sugar, or glucose. Nevertheless, the results obtained suggested that the carbohydrate in itself played some part in the production of rachitic symptoms. In view of my more recent experiments, however, it is difficult to believe that the rickets-producing effect of cereals is wholly due to their carbohydrate content, and I am at present engaged in finding the new factors involved. The most prominent fact brought out in the cereal experiments is that oatmeal has a greater rickets-producing effect under the conditions of these experiments than equal weights of flour, especially white flour, or rice. Since the amount of carbohydrate in oatmeal, wheaten flour, and rice is respectively of the order 65 per cent., 7.35 per cent., and 77 per cent.—that is to say, there is less carbohydrate in oatmeal than in the other cereals—it is manifest that the greater rickets-producing effect of oatmeal as compared with the other cereals cannot be due to its carbohydrate moiety.

In some way the effect of cereals is no doubt related to their property of producing growth, both in the sense of producing longer and bigger bones and an actual increase in weight. This action of cereal is best illustrated by contrasting its effect on the metabolism with that of fat. Adding more cereal to a diet already adequate causes young animals to increase more rapidly in weight, to develop a deposit of fat which is undoubtedly formed from carbohydrate, and to become more lethargic. Under the same conditions the addition of fat makes no difference to the rate of increase in body weight, for it neither increases the laying down of tissue nor is it deposited subcutaneously as *dépôt fat*. It is burnt up and increases the metabolism. These opposite effects of cereal and fat on the metabolism of young animals are most striking and have probably not received the attention they deserve.

Cereals, then, increase the laying down of fat and tissues generally, including the bones, and thereby make a greater demand on the calcification processes, so that any tendency to lag behind in this respect is increased by allowing the child or animal to eat a larger quantity of cereal. Increasing the bread, therefore, in a diet slightly rickets-producing only emphasizes the disease and causes the development of larger quantities of cartilage and osteoid tissue in the bones. This explanation, however, is not a complete one, for it does not satisfactorily explain the differences between oatmeal, white flour, and rice. In some series of experiments there was no obvious difference between the rates of growth or in the rates of putting on weight when oatmeal, white flour, and rice were the only variables, yet the rickets produced by oatmeal was much greater than that produced by equal quantities of the other cereals. Undoubtedly some other factor in oatmeal is at work which either prevents endochondral calcification or increases the formation of tissue at this point, thereby producing a relative lag in calcification at the ends of the bones. It does not appear to be the carbo-

ratio moiety, and as I pointed out in a previous Section the larger amounts of calcium and phosphorus in oatmeal discredit the explanation which centres round deficiency of these substances. Further experiments will have to be carried out before definite pronouncement can be made on this point.

FACTORS OF HYGIENE AND THEIR INFLUENCE ON RICKETS.

The two factors of hygiene that influence rickets, evidence of whose action rests on a definite experimental basis, are exercise and sunlight. The evidence that infection is of any importance in this respect seems to me too meagre at present for warrant discussion.

I have dealt elsewhere¹ with the exercise hypothesis and Findlay's claim¹² that it is the most important factor in the etiology of rickets, and will only state here that, in my opinion, the exercise taken by a child at the ordinary period of rickets development consists of small movements; also that this general activity depends almost entirely on its diet and not on its environment. Diet not only, therefore, has its direct action on the tissues of the body—including, from our particular point of view, the bones—but, by controlling the activity, has an indirect effect.

The second factor of hygiene—namely, sunlight—has quite recently come into great prominence as the result of experimental work, and demands closer consideration. The recognition of the antirachitic action of sunlight has been gradual and is the outcome of Huldshinsky's³ observations of the curative effect on rickets exerted by the ultra-violet rays emitted by the mercury-vapour quartz lamp. Later, he supplemented the ultra-violet ray treatment of rachitic children with sunlight, whereas Riedel⁴ treated cases of rickets by sunlight supplemented with ultra-violet rays on sunless days. Hess and Senger⁵ then showed that sunlight alone is capable of bringing about curative changes in rickety bones. There is now but little doubt that it is the ultra-violet rays of sunlight which are the effective agents. Many publications have appeared recently on this subject, and the action of sunlight in stimulating calcification processes in bone is generally accepted.

This effect on calcification of bones is of great interest, but even greater importance is the recognition that sunlight has much wider influence, especially in the case of animals on defective diets, for in these cases it is capable of stimulating their appetite and increasing the rate of growth and activity. Even cases of latent tetany (Sachs¹⁰) and definite tetany (Huldshinsky¹¹) have been cured by ultra-violet rays. It is evident, therefore, that the ultra-violet rays promote some chemical change in the body which results in profound modification of many activities. Since these rays have very little penetrating power it is probable that their action is on the skin, and that some powerful chemical substance is thereby liberated. Hess¹² has pointed out that the antirachitic effect of the ultra-violet rays is smaller in the case of black rats compared with white rats. Certainly in the case of puppies with dark hair the effect of sunlight in preventing the development of rickets, when placed on rickets-producing diets, is, in my experience, negligible. It is interesting that sunlight, when it strikes the skin, produces changes in the bones and general condition of rachitic children and animals in some ways comparable to the effect produced by giving cod-liver oil, and it seems possible that the fat-soluble vitamin is the substance liberated into the circulation by the action of the ultra-violet rays on the skin. If this is the case then sunlight and ultra-violet rays ought to have other specific effects, such as (1) the cure of xerophthalmia, when the diets remain devoid of this vitamin, and (2) resumption of growth in young rats when growth has ceased owing to lack of this substance in the diet. Should these results be produced by exposure of the skin to ultra-violet rays, no doubt will remain as to the chemical substance set free into the circulation.

The scientific importance of these facts is obviously great, for they appear to open up a new field in physiology, but, in evaluating their importance in the prophylaxis and curative treatment of rickets in children, we must not be carried away by the interest of the subject. It will be agreed that, if the sunlight has to pass through clothing, its effect on the skin will be greatly diminished, if not destroyed, and even in its passage through window glass its ultra-violet rays are lost. Then, again, it is customary for a mother in this country to prevent sunlight falling directly on the only uncovered part of an infant

out of doors—namely, its face. All things considered, the amount of direct sunlight falling on to the skin of a child in its first year of life, a time when it is most susceptible to rickets, must be very little. I am inclined to think that in this country at least the part played by sunlight in preventing rickets is small. If it be answered that rickets is rife in this country for the reason that children are not exposed to sunlight, then, I ask, are the excellent teeth and absence of rickets in the Eskimo in his natural surroundings due to exposure of the skin to the sun during infancy? In tropical countries, where less clothing is worn and more sunshine is obtained, the ultra-violet rays undoubtedly hold a place of greater significance, although even here nature tends to diminish such influence by depositing pigment in the skin.

If it should happen, as seems possible, that the chemical hormone liberated by the sunlight is the antirachitic vitamin about which much of my experimental work on rickets has centred, then it only serves to emphasize the importance of diet in the etiology of this disease. For, although we cannot control sunlight, we can control the diet and we can see that it not only contains an adequate amount of this substance, but that it is so balanced with other factors that full use is made of it in the metabolism of the child.

I suggest that the following statements will cover most of the conditions where diet and sunlight interact:

(1) That when a child is well fed the presence or absence of sunlight makes no difference to its health in so far as rickets is concerned.

(2) That in the case of a child fed on a mediocre, borderline diet, exposure of the skin to sunlight will probably prevent rickets.

(3) That in the case of badly fed children—that is, when diets contain much cereal and a deficiency of fat-soluble vitamin and calcium—sunlight will not prevent rickets, but may ameliorate the symptoms to some extent.

It will be seen that, as in the case of exercise, so in regard to this other condition of hygiene—namely, sunlight—I consider it to be of secondary importance to diet in the etiology of rickets.

DIET AND RACHITIC CHILDREN.

A typical diet that I give to children with severe rickets is as follows:

Milk, 1 to 1½ pints.
Beef dripping, 1 to 2 oz. with bread.
Meat, 1 to 2 oz.—usually raw scraped and mixed with potatoes.
One egg.
Milk pudding.
One orange.

This diet alone will bring about rapid improvement, but the process of healing is hastened by the administration of cod-liver oil, 1 to 1 drachms t.d.s. In a recent publication Findlay¹¹ states that cod-liver oil produces very little clinical improvement, although definite evidence of healing, as seen by radiograph, can be observed. He further states that the administration of cod-liver oil and phosphorus does not produce healing of bones any more speedily than that produced by massage and electricity, which, he says, takes two or three months before any change in ossification of the bone can be noticed. I have had no experience of massage and electricity as a treatment for rickets, but there is no difficulty in producing great improvement in calcification of bones by the above diet, especially if cod-liver oil be added, during the course of one month. More noticeable, however, is the improvement in the general condition of these children apart from the calcification of bone. The most lethargic and miserable of infants, even in the later old-standing cases when a marasmic and semi-paralytic condition has developed, become bright and active. So active, indeed, do they become, when treated in the above-described way, that in many cases their coats have to be netted. Children, in fact, react to diet in the same way as do puppies, and the influence of diet on muscular movement is so prominent that I am surprised no observations of this type have been made by the Glasgow workers. However small a kennel, and however unhygienic its surroundings, with no access to sunlight and no special precautions as to cleaning, a properly fed puppy will remain very active and free from rickets. It is equally easy, by improper feeding, to make other puppies listless and lethargic, with but little desire to run about even when placed

in open fields. By improper feeding I do not mean starvation, for these animals are usually fat and look well nourished. It is also a matter of common experience that diets of high cereal content more particularly produce fat, lethargic, and contented children, whose small movements and general activity are subnormal, although the other environmental factors may be good. Nothing is more dramatic than the change in behaviour produced in rickety babies when the diet is altered to the type previously described. Clinical improvement and increased calcification and growth of bone are synchronous, and both are obvious within a few weeks of giving the good diet.

It is true that cases of rickets in children occasionally appear where it is difficult to account for the disease on the basis of the facts as I have described them. Investigation often shows that these cases are associated with some exceptional condition—such, for instance, as premature birth, or twins, or, in some cases, the children may have just recovered from a severe infection. But these cases only indicate that we have still much to learn of the factors which control the growth and calcification of bone. In my experience, all rachitic children react favourably to a good diet such as I have described.

There is one point about this dietetic treatment of rickets that may give trouble—namely, the fat dyspepsia that cod-liver oil may produce in some cases, more especially if the other fat in the diet is kept high. Some children in the early stages of treatment can only tolerate a moderate amount of fat, and are made ill by 2 ounces of beef dripping and 6 or more drachms of cod-liver oil per diem. If this happens, all recovery processes cease, and the sickness and other symptoms may be severe. It is well in these cases to cut down all the fat in the diet, and, starting with smaller quantities, to increase it step by step.

DISCUSSION.

Dr. ROBERT HUTCHISON (London) said: Any contribution I can make to this discussion must be from a purely clinical standpoint, but it is perhaps not altogether superfluous to point out that in trying to determine the nature and cause of rickets clinical observation, if it be sufficiently extensive, may be just as valuable a guide as laboratory experiments. We may also legitimately inquire at the outset whether it is quite certain that one may safely argue from the experimental rickets artificially produced in animals to the disease as seen in the child. This inquiry is all the more pertinent when it is remembered that the experimental results seem to vary with the animal employed, whether dogs, rats, or calves. Leaving aside these preliminary questions, I think it will be generally agreed amongst clinicians that neither of the two rival present-day theories of rickets, the dietetic nor the hygienic, will by itself quite meet all the facts. Clinicians have long recognized that bad hygienic conditions and, in particular, want of sunlight favour the development of the disease. This was clearly pointed out by Chendale twenty years ago. On the other hand, it is difficult to believe that the hygienic factor is the only one concerned in the production of rickets, seeing that, as every clinician knows, the disease can be cured by altering the diet without any other change in the environment. If this were not so the outpatient treatment of rickets would be almost hopeless. It is for this reason that the great majority of clinicians have hitherto attached chief importance to the dietetic factor, and the kind of diet which is regarded as most apt to give rise to rickets is one which contains little fat and protein and a relative excess of carbohydrates, and chief stress has always been laid on the importance of poverty in animal fat. The question then arises, Is it deficiency of fat as such that causes the disease, or deficiency of a fat-soluble vitamin? This brings us to the vitamin theory, and here again the

clinician has difficulty in agreeing wholeheartedly with its advocates. The reason is that rickets may certainly develop on diets which cannot be by any means absolutely lacking in fat-soluble vitamin, even although they may exhibit a relative deficiency of it. The observations of Miss Chick on children in Vienna, and of Dr. Hess on rats, seem also opposed to an acceptance of the extreme vitamin view. It may be argued that the undoubted curative effect of cod-liver oil in the disease is in favour of the vitamin theory, but it was the experience of many clinicians during the war, when cod-liver oil was unobtainable and cotton-seed oil had to be substituted for it in out-patient practice, that the latter seemed to be almost equally efficacious as a curative agent.

It is interesting to note that the supporters both of the vitamin and of the "defective hygiene" theories seem to be gradually shifting from their original point of view. The former tend to speak now of a relative rather than an absolute deficiency of vitamin and to invoke as necessary concomitants an excess of starch in the diet and perhaps a deficiency of calcium and phosphorus. On the other hand Dr. Findlay, as a protagonist of the hygiene school, now tentatively postulates a possible "virus" as the exciting cause of the disease. If by this he means a microbe I think he will not find many clinicians to agree with him. That rickets is an infective disease is a hypothesis which is *a priori* extremely unlikely. Rickets has none of the usual clinical characters of such a disease, but suggests much more a purely metabolic disorder like gout or diabetes. It is quite likely that many factors, diietetic, hygienic, and other, acting singly or in combination, are able to bring about the general disorder of metabolism called rickets just as gout may be caused either by errors of diet or by insufficiency of exercise or by both. What we chiefly need, I would suggest, is a more profound study of the metabolism of the disease on lines such as those which Professor Noël Paton has initiated in his researches on the lipoids.

Professor D. NOËL PATON made the following contribution to the discussion.

Milk Fat.—I wish to consider first the practical question, Is there any evidence that milk fat (butter) is a potent antirachitic agent? not the academic question of whether possibly it may contain small amounts of some agent of this kind. It is a point of considerable practical importance, because, largely as a result of the memorandum issued by the Vitamin Committee of the Lister Institute and the Medical Research Council, there is a widespread conviction that milk fats are of primary moment in this respect, and much expenditure is being incurred to secure their supply. In the memorandum they speak of the antirachitic as identical with the "fat-soluble A growth factor," and they give certain directions for the prevention of rickets, stating that "milk and butter are the best sources of this antirachitic factor for young and growing children." They also publish a table giving the relative proportion of the antirachitic factor in different foods in which butter and cod-liver oil are placed equal at the head. The conclusions are avowedly based upon the partially published results of E. Mellanby. It is for this reason only that I must examine his evidence. He states, in his *Experimental Rickets* (1921, p. 18), that a diet of from 175 to 250 c.c.m. of separated milk and bread produces "rapid and marked rickets in well-growing pups." To argue from this that the development of rickets is due to the deficiency of a fat-soluble A substance in butter is hardly justifiable, since when the dogs reach the size of 4,000 grams and are then getting from 43 to 62 c.c.m. per kilo of body weight, the CaO intake is seriously reduced—to 0.07 to 0.1 gram per kilo. The normal retention on a diet adequately rich in CaO is about 0.15 gram per kilo. Thus two factors at least are involved—namely, decrease of milk fat and decrease of CaO. As regards the action of milk fats in preventing the onset of the disease, I can find definite experiments on only three dogs. Two remained free from rickets; one developed the disease (pp. 20, 23, 29; the last given also on p. 48). In the experiments on pages 28 and 37 butter fat was given, in one with linseed oil, in two with meat, which Mellanby states plays some part in preventing the onset of rickets. Yet one of these is noted as "practically normal," one as "nearly normal," which means that they had some signs of rickets, and one as "slight rickets." The contention that whole milk has a curative action seems based upon one experiment (p. 65), in which, after the development of rickets on crushed palm kernel, milk was substituted and improvement occurred (Figs. 15, 16, 17). That this was due to the milk fat is

dered doubtful by the next series of figures (Figs. 18, 19, showing still more marked curative changes, the palm not being continued with no change in the diet—an example of the spontaneous cure which makes the investigation of curative agents so unreliable. On the curative action of butter I can find only one observation on our dog (p. 66). It does not justify a conclusion being drawn. The evidence does not therefore seem to me to warrant the recommendations of the committee, and it is unfortunate that a scientific ally should, without more proof, have interfered in practical matters.

In our experimental work we have thought it necessary to use large numbers of pups of the same litter, since individual susceptibility makes observations of single pups, as adopted by Mellanby, quite unreliable. In 1918 we showed: (1) That pups (11) on from 100 to 200 c.cm. of whole milk (3 to 6 grams fat) and oatmeal porridge, kept in the laboratory, developed rickets. (2) That pups (5) upon skimmed milk (2.8 grams fat) and oatmeal porridge, when kept in the country, grew up without signs of rickets. In 1921 we recorded experiments (4) confirming our previous conclusions (1) and showing the following results: (3) That pups (8) might be reared in the laboratory free of rickets on separated milk and bread with only 0.5 gram milk fat per kilo of body weight, provided the diet yielded sufficient energy, and provided scrupulous cleanliness was observed. (4) That butter fat has no curative action in rickets. (1918 experiments—4 pups; 1921 experiments—4 pups). The results of Hess (*Proc. Soc. Exper. Biol. and Med.*, 1920, 21, 266) indicate that butter fat has no antirachitic action, either prophylactic or curative. McCollum, Simmonds, Nibley, and Park have arrived at practically the same conclusion (*Amer. Journ. Hyg.*, 1921, 1, 512). Hutelison's Indian results give no support to the view that milk fat is of special value, and we know that thousands of children grow up without rickets on less than a quarter of a pint of milk a day.

The evidence thus seems to be all against the importance of milk fat as an antirachitic agent. Miss Chick and her fellow workers seem to have given it up for cod-liver oil and sunlight.

Cod-liver Oil.—The old view of the clinicians that cod-liver oil has an influence in delaying the onset and hastening the cure of rickets has been supported both by Mellanby, whose conclusions are, in this case, based upon an adequate number of observations (9 dogs), and by such recent work as that of Hess, McCollum, and their co-workers. Their work, however, has gone far to disprove the connexion between the antirachitic agent in cod-liver oil and the fat-soluble A substance.

Other Antirachitic Agents.—Not only has cod-liver oil this prophylactic and curative action, but (1) we now know that sunlight and ultra-violet rays act in the same way; (2) we now know that healing of rickets in rats occurs during starvation; (3) we know that spontaneous recovery from rickets without change of diet frequently occurs (Mellanby, Figs. 18, 19, 20); (4) we know that a change in the salt ration of pigs, as demonstrated by Elliot and Orr, leads to a cure; and (5) lastly, the evidence afforded by McCollum and others shows that simple lowering in the phosphorus to calcium ratio in the diet may be associated with rickets-like changes in the bones of rats. This one naturally correlates with the decreases in the inorganic phosphates of the serum first observed in rickets by Howland and Kramer. But is this not merely an indication of an alteration in the metabolism of the much more important organic phosphorus compounds? Some factor other than the absence of a vitamin must be involved.

Calcium.—The influence of the supply of calcium requires more attention, although many investigations have been made since E. Voit's study. The supply of phosphorus is always adequate in any diet. Mellanby states that "plenty of calcium and phosphorus in the diet" tends to prevent rickets in puppies, but I can find no experimental evidence in his report to justify the conclusion (p. 52). I would ask him where it is to be found, and I would ask him if it is right to place butter among the foodstuffs rich in calcium, stating that it contains 0.37 per cent. CaO, while, at most, only about 0.04 per cent. is present. Egg yolk contains about 0.14 and not 0.4 per cent. Cabbage surely does not contain 0.45 per cent.: Sherman gives 0.063. This is an important matter, for he now states that abundance of calcium and vitamin A are often associated in foods. For observations upon diets poor in calcium and in vitamin A we have used bean meat and bread. Our experiments (4 dogs) show that pups may be reared free of rickets upon such a diet, if an

amount of calcium is added to the diet equivalent to that yielded by about 100 grams of milk per kilo—that is, 0.16 gram. On a low CaO intake of 0.035 gram per kilo osteoporosis and possibly rickets developed. This seems to me to indicate that the influence of the salts is prepotent. Pups at least can be reared without milk or cod-liver oil. I cannot understand the evidence upon which Mellanby concludes that meat retards the development of rickets. I find experiments upon 7 dogs on meat recorded and in all the pups developed rickets, that getting most meat becoming the most rickety. It seems to me to draw conclusions in spite of and not on account of his experiments. In these experiments the dogs were getting a totally inadequate supply of calcium.

Bread.—The theory has been advanced by several clinicians that excess of carbohydrates induces rickets. Mellanby supports this view, insisting that excessive bread is provocative of the disease, and he concludes that "probably the most common cause of rickets in children is a combination of relatively deficient antirachitic vitamin and excessive bread"—a very important practical conclusion, if true. On this subject I can find experiments upon only 5 dogs (p. 43) in which the intake of bread was measured. All developed rickets, as well they might, on a diet so poor in calcium. I calculate that he gave his dogs from 26 to 50 grams of bread per kilo per day. We have reared 16 pups free from rickets on separated milk with a much larger intake of bread—from 42 to 64 grams per kilo per day. In his conclusion (p. 75) he includes with "excess of bread" "other cereals." To-day he has given some results with oatmeal which raise the question of whether the cooking was adequate. Not a single experiment on these is recorded, although the calcium content of cereals differs greatly. On sugar, the only carbohydrate tested, I can find one experiment on 3 dogs, 2 of which got sugar, 1 of which did not. All developed rickets. On other carbohydrates there are no observations.

I do not think that on such evidence we are justified in concluding that bread, cereals, and sugar have so prejudicial an influence.

Infection.—The familial incidence of rickets and its association, in Glasgow at least, with overcrowding and bad association, the possibility of a microbial aetiology investigated. The

older workers and the more recent work of Koronchewsky do not seem to me to throw light upon the question, because infection must be from case to case by the blood through fleas, lice, or bugs, or through the alimentary canal or respiratory tract, possibly by faecal infection. To test these possibilities we have inoculated pups (3) with the blood from cases of active rickets, and we have added to the food of others (8, with 8 checks) faeces from cases of active rickets. Entirely negative results have been obtained. But this raises the question—Is rickets in dogs the same as human rickets?

What, then, is the present position of our knowledge of the aetiology of rickets? There is no evidence that it is caused by a lack of milk fat or anything connected with it. There is no evidence that it is caused by an excess of carbohydrates or of bread. There is no positive evidence that it is an infective process. Admitting that sunlight and cod-liver oil are prophylactic and curative, as they also seem to be in tuberculosis, is their absence the cause of the disease? It is true that in all probability by their systematic use many infants might be reared free of rickets who would otherwise develop the disease, but does that mean that their absence is causal? Children in the high Norwegian valleys far from a supply of cod-liver oil, and without sunlight for five months in the year, grow up free of rickets. It seems to me that these agents must act by producing such a change in the metabolism as enables the child to resist or to throw off the condition. Pups reared in subdued light are most lethargic, and I need only refer to the investigations of Leonard Hill on exposure to sunlight and air. Their influence on the general metabolism urgently requires investigation, and wild theories as to the production of fat-soluble A in the skin are better withheld till evidence is collected.

What the real cause of rickets is we know no more than Glisson did in 1650, or Soranus Ephesus in A.D. 100; and we know practically nothing of the modifications of the metabolism which are the essentials of the disease and which are the cause of the bone changes. Even the interpretation of x-ray pictures is not clear. Some appear to consider that the cupping at the end of the long bone is a process of decalcification, while it may simply be an abnormality in intracartilaginous ossification with a

persistence of the periosteal growth. I feel strongly that it is the duty of those of us who are trying to solve these problems not to work in isolation, but to combine and to devise and carry out a definite plan of campaign, and to refrain from theories till we have accumulated facts.

Professor KORENCHESKY (Lister Institute, London) said: On comparing these experiments with those of other authors, I am forced to the conclusion that the principal results are in agreement with Mellanby's experiments, and would appear to disagree with the results arrived at by other authors in their experiments with diets deprived of the antirachitic properties present in milk, some fats, and especially cod-liver oil—that is, diets deprived of the so-called vitamin A. Only Mellanby (in his experiments on puppies) and I (in my experiments on rats) managed to obtain rachitic changes of the skeleton. The circumstances under which, in my experiments, osteoporosis alone of the skeleton was obtained explain the apparent contradiction. The quite imperceptible transitions, in my experiments, from the histological picture of osteoporosis to that of rickets, as well as the fact that the skeleton can at the same time show both rickets and osteoporosis, demonstrate as follows: In osteoporosis, or rather, owing to the causes producing osteoporosis, the rachitic changes of the skeleton may remain latent, as an energetic formation of new bone is required for their manifestation. This supposition is further confirmed by the chemical changes of the skeleton, which are, on the whole, the same in all cases. Similarly, in human rickets, according to the opinion of the majority of investigators, there is no essential difference between osteoporotic and hyperplastic rickets, between latent rickets in cachectic children and rachitis florida in more satisfactorily nourished children. All the conditions which have a marked influence on the growth of tissues—that is to say, starvation, exhausting diseases, deprivation of substances stimulating the growth of tissues (vitamin), and so on—will conduce to the appearance of osteoporosis of the bones. The mechanism of development of this skeletal disorder has nothing in common with rickets, as the cause of rickets lies in the disturbance of calcium metabolism, while osteoporosis is caused either by delay in the formation of new bone or in the increased destruction of old. Then why is it that, when the organism is deprived of vitamin A, rickets is so frequently associated with osteoporosis? That unknown principle α , which goes by the name of vitamin A, has two chief properties: that of stimulating the growth of tissues and that of regulating the metabolism of calcium, particularly in the bones. McCollam and his collaborators suggest the existence of different vitamins acting on the two lines above mentioned. Up to the present time a complete separation of these properties of vitamin A has not been possible. In depriving an animal of vitamin A, the bone tissue is deprived of both the influences above mentioned, while the absence of a stimulant for the growth of bone in conjunction with its continued destruction must inevitably result in osteoporosis. In addition to this there is the osteoporosis-producing action of starvation due to the animal's loss of appetite. The increased number of osteoclasts is apparently caused by the destruction of the bone for the purpose of providing the organism with a source of energy during starvation. The possibility of the existence of compensatory mechanisms capable of replacing vitamin A to a certain extent, and their degree of development in different individuals, the varying power of resistance of the organism, its predisposition to disturbances of calcium metabolism, or, on the other hand, to disturbances in the growth of tissues, the presence of conditions which, apart from vitamin A, are capable of producing osteoporosis—all these factors, apparently, decide the question as to the principal character of the changes of the skeleton on a diet deficient in the antirachitic organic factor. The nutrition of the mother during lactation also strongly influences the power of resistance to rickets or the reverse in the offspring.

There is one more question to be touched on—namely, why in some cases a picture typical of rachitis tarda or osteomalacia is observed in the skeleton—that is to say, why, with an abnormal and sometimes very large amount of osteoid, there is an absence or only a slight development of changes in the cartilage typical of rickets (the proliferating cartilage being sometimes even diminished). The conclusions which may be drawn from my experiments are as follows: Rickets was produced in rats, provided the age was not greater than 3 to 6 weeks at the beginning of special feeding. When the

special feeding was started at the age of about 2 months a picture characteristic of late rickets or osteomalacia resulted—namely, the changes in proliferating cartilage were not well marked. In rats at the age of 3 months or older, in a rickets-producing diet is administered for about three months the changes occurring in the skeleton are either insignificant or show signs of mild late rickets or osteomalacia. Therefore my experiments corroborate the view that there is no essential distinction between rickets and osteomalacia, the only modifying influence being age.

Summarizing what I have said about the effect on the skeleton of the diet used by me, containing minimal adequate amount of calcium and deficient in the so-called vitamin A I consider it possible to draw the following conclusions:

1. The action of vitamin A on the skeleton is the result of the combined action of several factors, only some of which are known at present.

2. The primary and highly important function of vitamin A consists in its property of controlling the normal deposition of lime salts in the bone, and therefore normal calcium metabolism.

3. The second, and quite as important, function of vitamin A is its property of controlling growth and apparently the normal nutrition of tissues, the osseochondral in particular.

4. The third property of vitamin A is its power of inducing a normal state of appetite.

5. In my experiments on rats the elimination of the first function of vitamin A from the organism results in the development of rachitic affections of the skeleton; of the second and third in osteoporosis of the skeleton.

6. As a result, therefore, when the diet is deficient in vitamin A these three functions are eliminated simultaneously and the experimental rickets produced exclusively by this deficiency alone is associated with a more or less severe osteoporosis.

7. The absence or only slight development of osteoporosis in rickets produced by a deficiency of vitamin A in the diet might occur under the following conditions:

(a) When the deficiency of vitamin A, while not greatly undermining the general nutrition of the organism, is sufficient to affect calcium metabolism. Apparently, for the production of rickets in this case, it is necessary to increase the effect of such a small deficiency of vitamin A by the action of other factors which likewise disturb the calcium metabolism (for example, calcium or phosphorus starvation). Apparently such a method of the development of rickets is the most probable (but in my opinion not the only) one in the origin of human rickets.

(b) When the organism contains well-developed compensatory mechanisms capable of replacing (if only to a certain extent) the second and third functions of vitamin A.

8. The deficiency of diet of the mother in vitamin A results in a marked aggravation of the skeletal disorders of the offspring kept on a diet similarly deficient.

9. The state of nourishment of the mother during pregnancy and especially during lactation, is one of the most important conditions of the normal development of the skeleton of the offspring.

In the etiology of rickets and osteomalacia, the factors undoubtedly playing a great part in the origin of these diseases are deficiency in the diet of vitamin A (or of an organic factor closely connected with it), calcium, and phosphorus, or a disproportionate balance of the last two. Confinement, in the sense of insufficiency of light, fresh air, and muscular exercise, apparently also plays its part (the majority of the data in agreement with each other being in favour of the importance of light, particularly of ultra-violet rays). Therefore, apparently, rickets can be caused by any one of these etiological factors or by any combination of them. From this point of view there are several forms of rickets, which should be classified from an etiological standpoint.

Dr. DOUGLAS GALBRAITH (Glasgow) said: With regard to the question of diet in rickets, I should like to give briefly the results of an investigation I have been carrying on for over a year now at the Royal Hospital for Sick Children, Glasgow, under the guidance of Dr. Leonard Findlay. The chief object of this was to test the dietetic theory of etiology, with special reference to the fat consumption. The method adopted was to observe babies for long periods on definitely prescribed diets—fat-rich and fat-poor—and to note the incidence of rickets in the two groups.

The babies, some of whom were only a few weeks old when

ey came under observation, were seen frequently, weight parts kept, clinical notes made, and the children radio-applied regularly. The mothers all had written instructions the diet, and were questioned frequently, so that, although the children were not under direct observation as indoor cases as in the experiments described by Miss Chick, one could be fairly sure that the diets prescribed were being actually given. All those cases in which there was the slightest doubt were discarded. For a fat-sufficient diet milk and cod-liver oil were given in sufficient quantities was given up to ten months, and after that a general diet with milk, butter, soup, and gravy. The deficient diets were composed of milk mixtures containing 1 per cent., 1.5 per cent., and 2 per cent. fat. The diagnosis of rickets was never made unless the clinical findings were substantiated by a positive radiographic picture. In many cases the clinical signs were few, although the radiographic evidence was definite. The following table shows the results:

Analysis of Results (63 Children Observed).

Number of Children Observed.	Fat.	Nature of Feeding.	Number Developing Rickets.	Percentage Developing Rickets.	Percentage Developing Moderately Severe or Severe Rickets.
Winter:					
24	Sufficient	Artificial	21	87	66
17	Deficient	Artificial	2	70	41
18	Sufficient	Breast	13	72	44
4	Deficient	Breast	3	75	25
Summer:					
8	Sufficient	Artificial	1	12	0
12	Deficient	Artificial	3	25	0

It will be seen that of 63 children observed during the winter months 77 per cent. developed rickets, and the percentage in the fat-sufficient group is slightly higher than in the fat-poor. Furthermore, the degree of rickets is rather more severe in the children on a fat-sufficient diet than in those on a fat-poor diet. This experiment differs principally from those described by Miss Chick in that an ordinary fat-sufficient diet was given, whereas she added cod-liver oil to a similar diet. It is possible that the difference in results is attributable to some constituent of cod-liver oil other than fat-soluble vitamin. In the summer months the number of cases observed was smaller. The incidence of rickets was low, and the degree was slight in each case.

My conclusions are as follows: (1) Children on a definitely fat-sufficient diet developed rickets during the winter months. (2) The degree of rickets in children on fat-poor diets was no more severe than in those on sufficient diets. (3) Children on fat-poor diets remained free from rickets.

Dr. J. SIM WALLACE (late Lecturer on Dental Surgery and Pathology, London Hospital) said: Ideas with regard to the causation of rickets have recently been considerably influenced by the supposition that fat-soluble A played an important rôle in the development of the teeth. That lack of this vitamin cannot now be regarded as the cause of rickets is generally admitted; nevertheless the authors of the theory that absence of fat-soluble A causes dental hypoplasia have at stated clearly that they have now completely abandoned his idea. In a recent communication Mrs. Mellanby admits that there are "certainly" other causes of hypoplasia, but we want to know whether lack of fat-soluble A in the diet can be supposed to cause hypoplasia as frequently as does measles or scarlet fever, or for that matter any other single disease which may affect the life history of the ameloblasts or other epithelial cells.

The experiments and suppositions on which the vitamin theory rested never misled those who were well acquainted with the facts concerning the development of the teeth, but they certainly seemed to impress many outside the dental profession.

It may seem to enhance the importance of vitamins to observe them with marvellous powers. If it is possible to depict an abject animal in *extremis*, and then with the aid of minute doses of the required vitamin rejuvenate the animal as if by magic, then of course a sensational impression is made. Such results may well be true with regard

to beri-beri and other deficiency diseases, but the attempt to claim that totally different diseases are preventable or curable in a similar way seems hardly justifiable. We have been rather regaled with "the importance of the infinitely little" when the wonderful powers of a vitamin are to be shown on a graph or a screen; but when it is pointed out that children in these days are apparently more richly fed with regard to fat-soluble A than in past ages, it is openly proclaimed that an abundant supply of this vitamin is necessary, and something containing 250 times the fat-soluble A found in milk or butter is recommended to save our children from rickets, and the teeth from hypoplasia and dental caries. Even then clinicians often fail to note the marvellous effects claimed without a properly balanced diet, sunlight, and general hygienic conditions. Again, it may be possible to deprive puppies of calcium, phosphorus, and substances necessary for their metabolism in a laboratory so completely that the development of the teeth may be interfered with; but is there any evidence that this ever occurs among children so long as they are getting even a bare sufficiency of protein under any existing scheme of dietary, however eccentric it may be? The quantity of protein and the other ordinary constituents of the diet is massive; the quantity of fat-soluble A, if it be a vitamin, is negligible, for, as is generally recognized and as has been explicitly stated by Professor Halliburton, "the quantity of vitamin necessary in the diet is infinitely small."

In recent years dental examinations of multitudes of school children have been made, and one of the generalizations resulting from such examinations is that "the better the school the worse the teeth," which rather confirms the view, long held by dentists, that dental caries is not a deficiency disease; rather is it a luxury disease, depending upon the stagnation of easily fermentable and generally expensive carbohydrates.

But can we even regard the actual experiments which have been made on puppies as serious scientific evidence that lack of fat-soluble A produces dental hypoplasia? It was claimed that the special feeding of puppies had caused not only rickets but also dental hypoplasia. One might have thought that the first thing any competent experimentalist would have made sure of was that the hypoplasia had not been produced by other causes before the experiments with special feeding were commenced. Anyone acquainted with the development of enamel who is presented with a tooth showing a developmental defect is immediately interested in the conditions during, if not antecedent to, the formation of such enamel—that is to say, to conditions existing long before the eruption of the tooth. We have always recognized that rickets delays the eruption of the teeth. The specimens shown in the experiments referred to were from rickety puppies, so that presumably the eruption of the teeth had been retarded some weeks if not for some months. Now the enamel of the crown of a tooth is completely formed long before its eruption even in a non-rachitic subject. Consider the first permanent molar. In the human subject the tips of the cusps commence to calcify at or even before birth, and dentists recognize that the cusps of these teeth is associated with a corresponding age. The rest of the tooth is then gradually formed, and the crown is complete when the child is 2 years of age. But I want you specially to note that this tooth erupts four years later—that is, at the age of 6. Special feeding or anything else that happens to the child between the age of 2 and 6 has therefore no relation to hypoplasia of the crown of this tooth. Although the formation of the enamel in the first molar of a dog commences just before birth, growth being much more rapid than in the human subject, it is possible that the interval between the formation of the enamel and the completion of the eruption of the first molar in the dog may not amount to more than five or six months, or to seven or eight months when rickets is present. But it appears to have been during the three to six months immediately preceding the completion of eruption of the puppies' teeth that the special feeding which was supposed to produce the hypoplasia took place. In other words, to put it briefly, the hypoplasia existed for a month or two before the rickety feeding experiments were commenced. The only evidence of any attempt to correlate the effects of the feeding and the dental hypoplasia may perhaps be found in a statement by Mrs. Mellanby that "at intervals x-ray photographs were taken of the teeth developing in the jaws. This is not an easy matter in puppies and my results are not so successful

they ought to be." Much stress was laid on so-called facts," but when we investigate the facts we find that they are simply unjustifiable and misleading inferences.

Here let me refer to something of an amusing nature. In some of the exhibition specimens showing hypoplasia in the teeth of puppies, which was claimed to have resulted from the absence of fat-soluble A in the diet, the lower part of the crown of the first molar teeth—that is, the part nearest the neck of the tooth—had good enamel, although between this and the tip of the crown the enamel was hypoplastic. Now, if any part of the enamel was formed during the special feeding it must have been the part last formed—that is, the part at the neck of the tooth, because immediately the experiments were finished the jaws were treated with formalin and then preserved. Obviously, therefore, lack of fat-soluble A had cured the hypoplasia, if it did anything at all. We need not follow Professor Mellanby to Skye in his endeavours to associate the state of the teeth with fat-soluble A. His own laboratory shows us clearly all that is required to disprove his contentions.

The possible association of dental hypoplasia, rickets, and dental caries was investigated years ago by reliable observers in the medical and dental professions—not with regard to what happens in dogs, but with regard to children, which is more important, for it is this that we want to know about. Dr. G. A. Carpenter and Mr. Denison Podloy found that in ricketty children there is as a rule no deficiency of enamel,² and further, the latter authority, as the result of a subsequent examination of 500 boys and girls in the Evelina Hospital for Sick Children found that "there is no evidence to prove that caries is more frequent among rickety children than among those who are suffering from other diseases."³ Mr. Norman Bennett in a later investigation⁴ arrived at similar conclusions. He corroborated the views of previous observers, who attributed dental hypoplasia to certain diseases, such as measles, scarlet fever, whooping-cough, syphilis, dysentery, and digestive derangements not necessarily associated with rickets. Other investigators have made similar investigations and come to similar conclusions. But even though it were shown statistically that dental caries was more prevalent in children afflicted with rickets, this would not show that rickets causes or predisposes to caries. It would only corroborate what most of us believe, that excess of carbohydrate in the diet is an element in the causation of both diseases.

Consider the subject from another point of view. Hypoplasia is a very rare occurrence in the temporary dentition; and this has long been recognized by the dental profession. Recently Dr. A. T. Pitts found as a result of an examination of 5,000 temporary teeth that only about one-half per cent. were affected with hypoplasia. Yet caries is even more rampant in children's first teeth than it is in the teeth of adults, and for this reason I shall limit my concluding remarks to hypoplasia as it affects the temporary teeth. It is admitted that when hypoplasia affects teeth it is as a rule caused by other diseases than rickets; so we may say that although one tooth in 200 temporary teeth is affected with hypoplasia, only one tooth in 1,000 is affected with hypoplasia as a result of rickets. But rickets is now recognized to result from causes other than lack of fat-soluble A in the diet, at least as a very general rule. Let us suppose, however, that in 10 per cent. of cases lack of fat-soluble A causes or helps to cause the rickets, and we arrive at the conclusion that one tooth in 10,000 is affected with hypoplasia as a result of lack of fat-soluble A in the diet. Lastly, we must remember that hypoplastic teeth do not by any means always become carious. Though hypoplasia may and sometimes does predispose to focal carbohydrate stasis and consequently to caries, it does not always do so. Indeed, what strikes dentists most with regard to hypoplastic teeth is their ability to withstand the onset and progress of the disease, and medical men must have noted that the grossly hypoplastic Hutchinson's teeth are almost always free from caries.

So to sum up and keep to round numbers we may say that lack of fat-soluble A in the diet of children may be assumed to account for one carious tooth in 100,000.

It should nevertheless always be remembered that dental caries is a disease found as a matter of fact most abundantly among children who are fed with foods rich in fat-soluble A, and the sooner those who belabour "the importance of the infinitely little" learn to appreciate some sense of proportion the better for the rising generation.

Major H. S. HUTCHINSON, I.M.S., said: I wish to bring to your notice very briefly certain observations on dental caries in the Nasik and surrounding districts of the Bombay Deccan which I made just before leaving India last year. These observations are, I think, of some interest, not only from the point of view of the geographical distribution of the condition but also with reference to the occurrence of rickets in the Nasik district and to the dietary eaten therein. For the purpose of the present observations the Indians were divided into the same three classes as in my rickets inquiry—namely, (1) Mohammedans, (2) well-to-do Hindus, and (3) poor or lower-caste Hindus. Suffice it to say that the first two classes eat a dietary containing a fair amount of animal fat, about 35 grams on an average, while the third class eats only about 3 grams and at the same time consumes a much larger quantity of carbohydrates.

As a result of this inquiry it was found: (1) The number of teeth present per individual at all ages up to 40 is high, and that the percentage of caries present is very small. (2) There is practically no difference between the various classes as regards the amount of caries. It is evident that the poor diet of Class 3 has had little effect in producing caries. (3) The percentage of individuals without caries is high in all classes and certainly no less amongst the poor. We see then that the fat-poor dietary of the poorer classes has not led to the increase in dental caries which one would expect. I may say that in several cases I have seen the incisor teeth so ground down on their anterior surface that the central canal was visible in nearly its whole length, and that this was not accompanied by any caries. The incidence of dental caries bears no relationship to the occurrence of rickets. In Nasik I found rickets to be a disease of the well-to-do and not of the poor. The slide shows that caries is uncommon in all classes, and yet rickets is six times as common in the well-to-do, while this class eats a much better dietary.

I would like in conclusion to say that I cannot agree with Professor Mellanby in his statement that the general activity of the child depends almost entirely on its diet and not on its environment. If such were the case, judging from the dietary, the poor Indian children should be listless and rachitic, whereas my experience has been that they resemble Professor Paton's country pups in being strong sturdy specimens without a suspicion of rickets. Certainly this explanation of Professor Mellanby cannot explain the rarity of rickets among the poor Indians and its frequency among the much better fed rich, and it is totally insufficient for the cases of late rickets, which in Nasik is practically unknown among the poor. In considering the etiology of rickets the geographical distribution must be taken into account.

Dr. J. B. OAR (Rowett Institute, Aberdeen) said: I desire to deal with the importance of the mineral content of the diet. The characteristic feature of rickets is a disturbance of the mineral metabolism of the body. In the production of experimental rickets, therefore, until it is determined that the mineral matter of the diet is adjusted to the mineral requirements of the animal, it is premature to discuss the importance of any other dietary factor. Obviously the diet must contain all the essential minerals in sufficient amounts. Almost as important as the amount is the proportions in which they are present. The results of metabolic experiments which we have carried out show that the percentage utilization of calcium depends to some extent on the calcium-phosphorus ratio in the diet. It is not merely a question of there being a sufficiency of phosphorus. Inglo showed, years ago, that rickets in horses could be produced by a diet with an overwhelming excess of phosphorus. An excess of potassium interferes with the retention of calcium and a lack of proportion between sodium and potassium has been shown by Zantz to produce a definite pathological condition. Associated with this lack of balance is the influence of the form and combination in which the minerals are present. Even when dealing with such closely related foods as milks of different species, as has been shown by Uffemann, a growing animal can utilize a higher percentage of the calcium of the milk of its own species than of the milk of a different species. In the investigation of any dietary factor, therefore, unless the experimental ration contains all the essential minerals in the amounts and in the proportions that they are required, and in a form that they can be utilized, the result with regard to any other dietary factor is bound to be confused. In Mellanby's experiment on puppies, rickets developed on various diets consisting of rice, white bread, oatmeal, and from 170 to

250 c.c.m. of milk. In these diets the only constituent that contains a substantial amount of calcium is the milk. On Mollanby's ration it is impossible for the puppies to get more than 0.4 to 0.5 gram of calcium a day, whereas Voit has shown that a young dog of 3 to 4 kilos requires 0.5 to 0.7 gram of calcium a day, so that the diet contained an absolute deficiency of calcium. Further, in rice and white bread the small amount of mineral matter consists largely of phosphorus. The ratio of calcium to phosphorus is about 1 to 10, whereas in fresh milk it is roughly about 1 to 1. It is impossible to draw definite conclusions with regard to the influence of any other dietary factors on such rations, which are so deficient both in amount and in balance of mineral matter. Mollanby's experiments were repeated on pigs at the Rowett Institute, Aberdeen. Well-marked rickets developed in from thirty to forty days, but on the same rations with the mineral water adjusted by the addition of inorganic salts to make the amount sufficient, and the proportion of the different minerals resemble those obtaining in sow's milk, pigs from the same litter showed normal growth and perfect health. In other pig experiments it was found that when the mineral matter was properly adjusted no rickets developed on a diet of oatmeal, oats, and bran continued from the period of weaning at nine weeks until the animals were sexually mature. On the other hand on the same diet, without mineral adjustment, rickets developed even if cod-liver oil were given in amounts from 10 to 60 c.c.m. a day. Cod-liver oil has certainly some prophylactic value, and its influence is probably due to its effect in increasing the percentage assimilation of calcium or other minerals in a diet in which these are deficient. In these experiments on pigs and other animals we found that the closer the mineral content of the diet approximates to the requirement of the animal the less the influence of cod-liver oil. With regard to the relative importance of fat-soluble A and the proper amount and balance of minerals, there seems no doubt that the latter is the more important dietary factor so far as the production of rickets is concerned. All that has been said with regard to the evil effects of cereals and other carbohydrate-rich food can be explained on the ground of their poverty in minerals and the improper ratio in which these are present, and the curative effect of Mollanby diets, which contain such large quantities of milk and egg, can be ascribed as much to the mineral matter of them as to the hypothetical fat soluble A. The field in which information is most required is that of mineral metabolism. The work in this field is tedious, laborious, and unexciting, but it is likely to be as productive of definite and permanent results as the pursuit of the elusive vitamin.

Dr. WALTER ELLIOT, M.P., said: To-day's discussion shows very clearly how easy it becomes to concentrate on one part of a problem to the exclusion of the whole. When, for instance, Dr. Leonard Findlay concentrates on the probability of a microbial infection as the cause of rickets to the extent of denying altogether the influence of diet, it seems a position which cannot be maintained in view of the fact that rickets can be produced by an experimental diet in the dog (Mellanby), the rat (Korenchevsky), and by Dr. Orr and myself in both pigs and sheep. In any remarks which I have to offer I cannot speak first hand from the point of view of the clinician but only from that of the experimentalist. Nevertheless we must admit that everything we say must in the long run be subject to the verdict of the clinician. The results of experimental work, however, seem to point clearly towards diet as a very important factor in the onset of this condition, and to this extent I find myself in agreement with Dr. Mellanby. The particular food substance or quality governing the onset of rickets is a much more debatable point. It has been pointed out by the previous speaker that not only the quantities of mineral supplied but their ratio must be taken into account. This requires the greatest possible emphasis. Unknown bodies must not be postulated till complete allowance has been made for the known. For instance, minerals are supplied by Mellanby in one series of experiments in a "salt mixture" consisting of common salt only. McCollum, on the other hand, using a salt mixture based upon the ash of cow's milk, gives at least nine elements—sodium, chlorine, magnesium, sulphur, phosphorus, potassium, calcium, iron, and iodine. It seems here that the obsession with the presence or absence of "fat-soluble A" has led Mellanby to a neglect of other necessary requirements of the body. Similarly, great theories have been based on experimental work on rats. In Koren-

chevsky's striking work he uses as a basal diet a food with a salt mixture similar to that of McCollum. But this salt mixture follows the ash composition of cow's milk. There is not a single accurate figure upon rat's milk in existence—quantity, fat content, ash, are all alike unknown. Again, the remarks of other speakers upon confinement as a dominant factor ignore the fact that Korenchevsky found this to have no influence on rats. I also have found in work upon sheep that animals ranging freely in the open upon a natural diet could develop the illness. As a matter of fact, it is only during personal experimental work that one realizes how rough and ready is all the research upon mineral metabolism. Mineral substances are usually administered in a mixture corresponding to the ash of cow's milk. It is a pure assumption that they are here found in the state most suitable for assimilation by a young animal of this or another species. More facts on mineral metabolism are urgently required.

Dr. LEONARD FINDLAY, in reply, said that the discussion had been very important from both the academic and the practical points of view. He had limited himself to the clinical field. Changes which occurred in the rat and the dog did not necessarily happen in the child. Ossification of bone could be modified in many ways by experimenting with calcium, phosphorus, fat, etc., but a deficiency of any of these substances did not cause rickets. The fact that there were so many conflicting experiments showed that diet had nothing to do with it. If there were a combination of dietetic causes why did rickets occur only in the poorer classes? We should get away from the idea of lack of something. He disagreed with Dr. Hutchison that rickets could not be an infection. He congratulated Dr. Mellanby on his clinical results. He himself was not so successful. Anybody, however, could cure rickets in summer. He disagreed with Dr. Mellanby on the question of exercise. Babies were in the habit of exercising themselves all day. The cause of rickets was as yet undiscovered. We might be able to disprove Chendlo's statements, but we could not put anything in their place.

DISCUSSION ON THE TREATMENT OF TUBERCULOSIS OF THE CERVICAL GLANDS.

OPENING PAPER

BY

JOHN FRASER, M.C., M.D., F.R.C.S. EDIN.

I am glad that those who are responsible for drawing up the programme of the meeting have chosen this subject for discussion. The disease (at least in certain localities) is so frequent that its efficient treatment must be of interest and importance to the practitioner, and yet, in connexion with this all too common condition, though an enormous amount of literature has accumulated around the subject, there is no definite unanimity of opinion regarding the most efficacious methods of treatment. Too often the literature represents the extremes of opinion, and one looks in vain for some moderate view, that being the one which is generally acceptable to the majority. It seems to me that at a meeting of this description—one representing all shades of opinion and varieties of interest—it should surely be possible to formulate a group of common-sense rules which will guide the practitioner in his advice to his patient.

There are few subjects which show such a wide divergence of opinion. There are many men with experience in this branch of work, for whose opinion one has the greatest respect, who believe that it is incorrect ever to advise operation in a case of tuberculous cervical adenitis; on the other hand, there are physicians and surgeons of repute who advise operation in every instance, irrespective of the condition of the gland or the type of tuberculous disease with which it is affected. Again, those who advise operative interference differ widely in their ideas regarding the type of operation to be adopted. To some, operation means incision and curetting, to others it infers a complete removal of the cervical glands inclusive of and in the neighbourhood of the affected area, and there are a few who would be content with drainage of a tuberculous abscess when such develops. Someone must be in error, and it should surely be possible to formulate a definite scheme by following which one may be assured that one is doing the best possible for one's patients.

Personally I rather pride myself that I do not hold any extreme view—when I have finished this paper you may not agree with me—but I teach the student (the practitioner of to-morrow) that a moderate view is the correct one, a view which believes that under certain conditions there is a very definite place for conservative treatment, while in other circumstances there should be no hesitation in advising radical operative interference. The essential is to know when to advise the various types of treatment, and, further, to explain the reason for your choice to intelligent parents or patients.

Perhaps I ought to give some guarantee for the opinions which I express; the guarantee is based upon some 2,000 gland cases, for the treatment of which I have been responsible during the past ten years.

I do not intend to trouble you with any detailed account of the disease; my intention is to express my views upon treatment; but, as a rational treatment must essentially be based on factors of etiology and pathology, there are certain points in the clinico-pathological history of the disease which I wish to bring forward. I do so because these several factors seem to me to be the essential items upon which a logical and successful treatment must be based.

I.—A Distinction between Blood and Lymphatic Modes of Infection.

This is one of the points upon which my later argument is based, and therefore I desire to be definite. I wish to distinguish clearly between glands which have been infected with tuberculosis via the blood stream and those which have become diseased by a lymphatic spread from a local focus of infection. The question may be asked, How is one to distinguish between these two modes of infection? I know of two methods, one clinical and one pathological.

The clinical test depends upon the distribution of the diseased glands: a scattered, haphazard, and often coincident appearance of multiple diseased glands in areas unconnected by lymphatic vessels suggests a blood infection, while the local development of a tuberculous gland, the disease remaining for a time localized to that gland or its immediate neighbourhood and afterwards spreading to actually adjacent glands, suggests a lymphatic infection, more especially if the affected glands lie in lymphatic connexion with such an obvious area of absorption as the tonsil.

Pathologically there is a test which one is able to demonstrate at operation, but, being dependent on morbid anatomy, it is not of value from the clinical pre-operative standard. I may be permitted, however, to mention the detail. If two tuberculous glands in early stages of the disease are cut in longitudinal section, one being the result of a blood infection, the other due to a lymphatic spread, it is possible to distinguish between them, because in the case of the blood infection the early disease is central, while in the lymphatic spread the disease is distributed as groups of follicles around the periphery close underneath the capsule, in what may be termed the "corridor of the gland."

Of the two possible methods of gland infection—(a) by blood stream, (b) by lymphatic stream—it is correct to state that where the cervical disease of children is concerned a figure of over 90 per cent. represents the proportion of occurrence of the lymphatic infection. I believe that it is of primary importance to draw this distinction, and my subsequent remarks may be taken as applying to the common variety—the tuberculous gland which is the result of a lymphatic spread from a local area of absorption.

II.—The Proportional Distribution of the Gland Groups Affected.

In my experience the distribution of occurrence of the lymphatic variety is somewhat as follows:

Locus of Absorption.	Glands Affected.	Percentage Proportion.
Faucial tonsil	Jugulo-digastric group	80
Naso-pharyngeal adenoids ...	Post-carotid group	12
Carious teeth	Submaxillary group	8

There is a small percentage of cases which has not been included in this grouping—the cases in which the cervical disease is first noticed in the supraclavicular region. The majority of these are examples of a spread from the

mediastinal or bronchial glands. The occurrence of the variety is so rare in children, however, that I have not included it.

III.—The Lymphatic Type of Cervical Glandular Tuberculosis is for a Time a Local Manifestation of a Local Infection.

In many children the enlarged tuberculous gland is the first macroscopic evidence of the disease. The organisms have gained entrance through tonsils, adenoids, or carious teeth; they have extended by the lymphatics to the nearest group of lymphatic glands; they have become arrested in the lymphatic network of the gland, and it is their presence in the gland over a certain period of time which results in tuberculous adenitis. Now if you consider the position for a moment you will realize the importance of this sequence of events. From a local area of absorption there is a local manifestation of the disease, and for a certain period of time—the exact length of which we cannot at present define—the disease remains a local manifestation; an intraglandular tuberculosis. A parallel to this is not common in pathology. Where tuberculosis is concerned a somewhat similar condition is observed when the pathologist's wart develops, and there is a resulting infection of the epitrochlear and axillary glands, but in every other variety of tuberculosis the sequence is different. Therefore, at the risk of reiteration, I wish to insist upon this point—that in many cases cervical glandular tuberculosis is a local manifestation of a local absorption, and the glandular disease remains for a time the only manifestation of the disease apart from such infection as may exist in the area when the absorption occurred or in the lymphatics which conducted the disease.

IV.—Cervical Glandular Tuberculosis of the Lymphatic Type is Unassociated in its Early Stages with a Blood Infection.

There is a point in the teaching repertory of Sir Robert Philip which has always impressed me: it is the insistence he lays on the fact that tuberculosis is a systemic disease, and when he uses the term "systemic" I presume he means that the disease is essentially a general one with local manifestations at selected points. In many cases this is undoubtedly the correct view to take of the disease. Pulmonary tuberculosis in its various forms is invariably associated with a blood infection before it comes under the notice of the physician; bone and joint tuberculosis must of necessity be accompanied by a tuberculous septicaemia, because the foci are the local manifestations of a general infection; tabes mesenterica and tuberculous peritonitis are accompanied by a generalized infection before they become sufficiently definite to attract clinical attention; but in the cervical glandular tuberculosis of children—in the tuberculosis, for example, of the tonsillar or jugulo-digastric group which forms 80 per cent. of the cervical disease—we have an outstanding peculiarity: the disease remains for a certain period unaccompanied by a general infection; there is tuberculosis of the lymphatic gland or glands without the accompaniment of a bacemic involvement. The actual period of time which elapses between the original development of the disease in the gland and the involvement of the blood stream is probably considerable.

V.—Tuberculous Cervical Adenitis is in its Early Stages a Purely Tuberculous Infection.

I am not sure that we fully appreciate the importance of this fact, but the reality is brought out when we contrast cervical glandular tuberculosis with pulmonary tuberculosis. In the latter a mixed organismal infection is present early in the disease, and probably many of the general symptoms are originated and aggravated by the mixed infection. But in glandular tuberculosis, and especially in cervical glandular tuberculosis, the infection remains purely tuberculous except under two conditions—unwise operative interference, and the periodic attacks of subacute lymphadenitis and periadenitis, to which I shall allude later.

VI.—The Pathological Changes which a Tuberculous Lymphatic Gland Undergoes.

From what we have seen of the disease we recognize three pathological types—the caseating, the lymphoid, and the fibrous. The caseating variety is the most common. I do not know in what proportion it occurs, but it must form a very large percentage of the whole. The caseating variety

passes through a distinct sequence of changes. An intraglandular tuberculosis develops. Intracapsular caseation occurs, and during this period the gland becomes subject to attacks of periadenitis, which are interesting in so far as they temporarily alter the clinical picture. The explanation of the periadenitis is probably a superadded pyogenic infection—an infection with which the gland could normally deal, but which, the gland being dovitalized, with a proportion of its lymphoid tissue replaced by tuberculous disease, results in congestion, oedema, tenderness, and swelling of the affected gland. Periadenitis is generally the signal for the next stage of the sequence; the caseation appears to be stimulated by the superadded infection—it makes its way through the gland capsule, and the disease is now not only intraglandular, but there is, in addition, a periglandular tuberculous abscess. In a neglected case there are the later stages of subcutaneous abscess in addition to the periglandular and intraglandular foci, and, finally, a sinus or tuberculous ulcer of the overlying skin or mucous membrane.

The lymphatic type is comparatively uncommon; it is apt to be mistaken for Hodgkin's disease. There is little tendency to caseation except in the later stages of the disease, the glands remain discrete, and, unless caseation occurs, there is little tendency to periadenitis. This is a digression, and I shall allude to the point again; but I may say at this stage that, while the lymphoid type of disease is an easy one on which to operate, in so far as the glands separate readily, it is unsatisfactory in so far as recurrence is common unless definite precautions (to which I shall allude later) are taken.

Fibrous tuberculous adenitis is the least common type in children; in this respect it is distinctive from the adult disease, which is so often fibrous in character. The glands are small and hard, with usually some central caseation. From the surgical point of view it is an undesirable variety of the disease on account of the tendency which there is to form adhesions to surrounding parts.

VII.—The Importance of the Bovine Bacillus as the Causative Factor of Glandular Tuberculosis.

In Edinburgh two questions are repeatedly put to us:

How do you explain the large proportion of cervical glandular tuberculosis with which you have to deal in contrast with other centres? and

How do you account for the fact that a large proportion of the cases which you treat appear to be of a more severe and rapidly caseating type than that commonly met with in other centres?

It is rather difficult to give a definite answer to these two questions, but undoubtedly the answer to the first depends to some extent on the large proportion of cases which are due to an infection with the bovine type of bacillus. In 1912 and the succeeding years Mitchell reported a proportion of over 90 per cent. of the cervical glandular tuberculosis of children as being due to a bovine infection, and, though such a high proportion has been questioned, Wang later reported results which to some extent confirmed Mitchell's observations.

Such a high proportion of bovine infection can only mean unusual exposure to a milk infection, and it is possible that in this source we have the answer to the first question. That the question of the relatively high proportional occurrence of tuberculous glands in Edinburgh and district is a proper and pertinent one is clear; in the month of May, 1919, 82 new cases of cervical glandular tuberculosis came under my own observation.

If the second question is a correct one, I confess I find it difficult to know how it should be answered, unless it be that the answer to the first also explains the second—that a bovine glandular infection is more likely to run a subacute course with early caseation than a human infection. On this point, however, I have no reliable information.

VIII.—Questions of Age and General Condition of the Patient.

Under this heading there are one or two clinical points which I wish to consider. If children become infected with the disease in the first year of life my experience has been that almost invariably the disease makes rapid progress. There is an early tendency towards caseation and periadenitis, the disease rapidly spreads to a wide distribution, and comparatively early in the sequence there is an infection of the blood stream. With each successive year of life up to the time of puberty there is a gradually increasing resistance to the disease.

The other clinical detail is that certain types of glandular tuberculosis are associated with very distinct signs of a tuberculous toxæmia, while other types show little or no general symptoms. In one case there is a comparatively slight local disease, and yet the child is pale, listless, and anæmic, while in another case with a much more extensive local disease general symptoms are to all intents and purposes absent.

A Summary of the Clinico-Pathological Points which have a Bearing on Treatment.

I have made it clear that I have no intention of attempting a systematic description of the disease; instead I have indicated certain points which in my opinion have to be considered before a reasoned opinion can be given regarding the best method of treatment. I would therefore summarize the points as follows:

1. A distinction must be drawn between lymphatic and hæmic modes of infection.
2. A lymphatic glandular tuberculosis is for a time the only manifestation of the disease, apart from infection which may exist at the site of absorption or in the connecting lymphatics.
3. A lymphatic glandular tuberculosis is not at first accompanied by a blood infection.
4. With the exception of operative interference and the completion of periadenitis glandular tuberculosis is a purely tuberculous infection.
5. There are the three pathological types of the disease—the common caseating, the lymphoid, and the fibrous—and each of these has characteristics which influence the question of operative interference.
6. A large proportion of glandular tuberculosis owes its occurrence to a bovine infection.
7. In children of 1 year and under glandular tuberculosis tends to run an acute course with early infection of the blood stream.
8. Certain children suffer greatly from a tuberculous toxæmia, while others, with possibly much more extensive local disease, show few or no general symptoms.

It is upon these facts that our ideas of treatment are based, and I shall endeavour to indicate to you what these views are.

The Lymphatic Type of Cervical Glandular Tuberculosis is a Preventable Disease.

This is a truth which can scarcely be insisted upon too frequently. You will notice that I distinctly state that the provision applies to the lymphatic variety, but even so, what does it mean if the lesson be efficiently learnt? It means possibly the exclusion of 90 per cent. of cervical glandular disease, and very likely a great diminution in the remaining 10 per cent. It is not for me to indicate efficient preventive measures, but I would mention two, and, if these were insisted upon, an improvement would result. They are the sterilization of every drop of milk which the child consumes until it reaches the age of 5 or 6 years, and the exercise of care that the child does not come into contact with a case of open tuberculosis. Insistence on the latter point should surely be a simple enough matter, yet it is extraordinary how blind parents may be to the possibility. Only the other day a child was brought to my notice suffering from extensive glandular tuberculosis. The child was accompanied by its mother and a nurse. The mother, who was apparently a sharp, intelligent woman, was exceedingly exercised about the explanation of the development of the disease. She was fully alive to the importance of milk sterilization, and she assured me that this precaution had been taken. I had meantime noticed that the child's nurse was wearing a small surgical dressing on her neck, and investigation showed that the girl had chronic glandular tuberculosis with a small discharging sinus. The child was subsequently operated on, and the bacteriologist reported that a human bacillus had been isolated from the child's infection. It is scarcely credible that such an obvious and preventable source of infection could have been overlooked, yet I assure you my report of the circumstances is correct, and a similar position, I have no doubt, frequently arises.

Have we Evidence that Glandular Tuberculosis can be Completely Cured by Non-operative Remedial Measures?

I can imagine the storm of indignation which even the suggestion of a question of this kind will arouse; but none the less it is a fair and proper question to ask, and it is one upon which we have a right to expect demonstrative evidence on one side or the other. When I use the word "cure" I mean the complete disappearance of the disease from the gland. I do not mean encapsulation of the disease by fibrous tissue and a shrinkage of the hitherto enlarged gland.

You will agree with me that the question is a very vital one, and I do not know that we have any definite evidence to give in confirmation of the positive reply which I feel sure all of us would like to give. I can bring forward one or two facts which would seem to imply that many cases which we hoped were cured have been examples of localization and arrest of the disease, but not of cure in the sense which I have defined. During the later period of the war and the succeeding months there was a marked increase in the number of cases of glandular tuberculosis. I do not for a moment believe that such an increase was the result of greater exposure to infection; I believe that the cases responsible for the augmentation were those in which the disease had become arrested either spontaneously or through remedial means, and the lowering of vitality, combined with the diminished ingestion of animal fats which occurred at the period I have mentioned, led to a weakening of the encapsulating barriers and a recrudescence of the disease.

It is a matter of common knowledge how frequently one of the exanthemata is followed by the appearance of enlarged tuberculous cervical glands. It must very rarely happen that the tuberculous infection is successive to the non-tuberculous—it is rather the lighting up of a latent tuberculous infection, and I have observations of many cases in which conservative measures had been adopted with apparent cure, only to find a fresh and virulent recurrence of the disease after an attack of measles or whooping-cough.

The last point I bring forward, which makes me wonder if sometimes we are not too sanguine about cases of conservative cure, is one which is capable of direct demonstration. Sometimes it becomes necessary to operate upon cases which have had a prolonged course of conservative remedial measures. I have taken special pains to investigate each of these cases which has come under my observation, and in every instance I have succeeded in demonstrating live tubercle bacilli in the interior of the glands. I am fully alive to the antagonism which such a statement as this will arouse. I fully appreciate, also, that "one rose does not make a summer"; but "a straw shows which way the wind blows," and I have a suspicion that it would be well for us to investigate more fully the possibility of a complete conservative cure occurring.

You will appreciate what an important point this is. Am I to say to my patient, "Under favourable conditions it is possible for the disease to be completely eradicated by conservative measures," or am I only at liberty to say, "Under favourable conditions we can succeed in so isolating and circumscribing the disease that it will cease to be an actual menace to you, though you must be careful that at some future period a recrudescence does not occur"? I wish to make it clear that I am talking of the local disease, not of a blood infection; of the organisms which are locked up within a barrier of fibrous tissue, not of those which are circulating in the blood stream. I have no fear of the latter, but from what I have seen I am sometimes doubtful whether a tuberculous gland which has undergone caseation can be considered capable of complete cure by conservative means.

What is the Ideal Treatment of a Tuberculous Cervical Gland?

I suppose we must regretfully confess that we possess no direct and specific antibacterial agent for tuberculosis; our most successful remedies act by such means as focal reactions and stimulations of the body resistance. That being so, if the position of affairs is such as I believe it is in the lymphatic variety of cervical glandular tuberculosis, that from a local area of absorption there is a local and circumscribed glandular demonstration of the disease, in the absence of a specific remedy for that disease undoubtedly the ideal treatment consists in removal of the affected gland group, with a suitable elimination of the area through which the absorption occurred.

The position is that a bacterial poison for which at present we possess no direct remedy gains entrance into the lymphatics, and is for a time arrested in a definite group of lymphatic glands. If we recognize this position we must ask ourselves if we are really justified in adopting a conservative attitude, in saying, "The infection has gained entrance, but I propose to leave it *in situ* and to trust to the general resistance of the body and to certain local congestive means to overcome and to isolate the disease." Whichever method you choose, I think it is but fair in an early case of lymphatic tuberculosis to lay these possibilities before patients or their

advisers. To my mind there is safety in the early operative removal, while the second possibility may involve enormous risk.

I know two arguments at least which will be advanced to contradict this line of early operation in the lymphatic type of the disease. It will be said that the glandular disease is so easily disseminated that to guarantee its complete removal is impossible. Those of us who have had an opportunity of operating upon a number of these cases know, however, that the disease is localized in its early stages, and remains so for a certain period of time. Another argument brought forward will be that operation is not justified at such an early stage of the disease, but the early operation in the lymphatic variety of the disease is the very basis of the ideal treatment.

I would express my creed in these words:

I believe that where children are concerned 90 per cent. of cervical glandular tuberculosis is the result of a lymphatic spread from a local area of absorption.

I believe that for a considerable time the disease remains limited to the gland or group of glands, and infection of the blood stream is a late complication.

In view of the fact that we possess no specific antibacterial agent to overcome the tubercle bacillus, I believe that the wisest course is to remove completely the affected gland or group of glands before the disastrous complication of blood invasion or dissemination occurs.

Now, to these statements I wish to add one qualification and it is an important one—it is relative to the question of operation. I believe that the whole success of surgical treatment in these cases depends upon the thoroughness with which the operation is performed. I am utterly opposed to the method of incision and scraping of the gland; it does not pretend to eradicate the disease, it increases the risk of dissemination by destroying limiting barriers, and sooner or later it ends in a secondary infection gaining entrance to the wound—in fact, it leads to each of the very complications which one is most anxious to avoid. It is this procedure of incomplete interference which has been responsible for the dissatisfaction with which operation is associated in the minds of many.

This is not the place to enter into a detailed account of the operation, but I would mention two facts in relation to it. Probably 80 per cent. and more of the cases call for removal of the jugulo-digastric group, and, as this group is in close lymphatic connexion with the posterior carotid chain, the operation is not a complete one unless this group too is removed. The removal must be radical and complete.

The second fact is this—out of interest in the subject I have looked over the figures of the operation cases for which I have been responsible. I have performed the operation of removal of the cervical glands on 1,428 occasions; as far as my knowledge goes, in seventeen of these cases minor secondary operation was necessary; the mortality was less than 1 per cent. In fact, it ranks as one of the most satisfactory surgical operations which we are called upon to perform. I can demonstrate, and will willingly do so at any time, hundreds of children who have been completely freed from the burden of tuberculous infection with all the risk it entails by a comparatively simple, early, complete surgical operation.

Such is one aspect of the problem, but there is another side about which we are just as definite. I believe that under certain conditions operative interference is strongly contra-indicated, and, as this paper has already reached to a most inordinate length, I shall do no more than tabulate what I consider are the contraindications to operative treatment.

Contraindications to Operation.

1. If there is reason to believe that the glandular infection is a blood-borne one.
2. If the distribution of the glandular disease is haphazard and irregular, such a qualification being strongly suggestive of a blood infection.
3. I do not advise operation in the fibrous type of the disease.
4. It is inadvisable from every point of view to undertake operation in cases which have been previously treated by incision and curetting.
5. As a general rule I do not advise operation in the first year of life.

In addition to these, which I look upon as absolute contraindications, there are three qualifying statements:

(a) I never undertake any operative interference during the stage of peridontitis. I advise instead that the gland be fomented with a saturated solution of magnesium sulphate until all signs of the peridontitis have disappeared.

(b) In the lymphoid type of glandular tuberculosis I insist that, if operation is to be done, it must be followed by a series of exposures to x-ray therapy.

(c) If the child is suffering from a tuberculous toxæmia, I advise a short preliminary course of tuberculin prior to operation. I do so because my experience has been that immediate operation without this precaution is liable to be followed by a degree of shock quite out of keeping with the severity of the operation.

But, someone will say, you have omitted to mention the type of case which is the most common of all, the case in which there is a tuberculous abscess present, either intra-glandular, periglandular, or subcutaneous. My answer is that, if the case does not otherwise come under any of the contraindication headings which I have mentioned, the presence of the abscess need make no difference. The incision is so planned that it does not pass through the skin immediately overlying the abscess; the abscess cavity can be evacuated without any fear of infection of the wound surface; the underlying glands are removed, and the abscess walls are sterilized with iodoform and bismuth paste. The post-operative results are as satisfactory as in an uncomplicated case.

I have purposely avoided any description of the conservative measures which are employed, but I may say that there are four procedures we favour—general hygienic treatment, the external application of Moro's ointment in its varying strengths, Bérancet's tuberculin internally, and in the lymphoid type of the disease x-ray therapy.

DISCUSSION.

The PRESIDENT (Sir Herbert Waterhouse) said that the thanks of the Section were due to Mr. Fraser for his clear and most interesting paper. He agreed with nearly every point that had been brought forward. He emphasized that tuberculosis of cervical glands was a local infection, and that the patient was cured if they were radically removed. He knew of no other cure. Recrudescence of the disease in glands that were considered free from infection was well shown in two of his cases. Some years ago two children with tuberculous glands came to his out-patient department. The mother declined operation. Rather to his surprise the glands subsided and became small and fibroid. Seven or eight years later, when the children were aged 14 and 15, they got measles. The glands became swollen, broke down, and suppurated. Those cases would have been reckoned as cures had he not chanced to see them again. He agreed with Mr. Fraser's three types of cases and also agreed in thinking that the fibroid and lymphatic types were best left alone. In the lymphatic type the operation had to be very extensive. A dissection from jaw to clavicle might be needed, and in a few months the glands would return and seemed to be as large as ever. There was one question he would like to ask Mr. Fraser. He could not understand the prevalence of bovine tuberculosis in Edinburgh. In London the human variety was relatively common. Could Mr. Fraser explain this? Another point he would like to bring forward was the effect of tuberculin treatment. For the last two or three years he had a growing conviction that with a bovine lesion human tuberculin gave the best results and vice versa. Of course it was difficult to demonstrate this, but he felt convinced that it was so. If he were asked, When was the best time to remove tuberculous glands he would reply, When they were freely movable, not when fixed by perianitis. Operation should be performed early.

He wished to enter a protest against the use of x rays in the treatment of tuberculous glands. With enormous glands of the lymphatic type where operation was inadvisable they might do some good by reducing their size, but in the generality of cases he was totally opposed to their use. Of late, owing to x rays, excisions in private practice had become increasingly difficult. An enormous amount of fibrosis took place after many exposures and the glands became firmly bound down. He had never seen a cure by x rays, but had come across numberless cases where the removal of the glands was rendered a difficult or dangerous operation.

Mr. GREY TURNER (Newcastle) said that he was sorry that he was called upon at this early stage of the proceedings because he was unable to differ from the previous speakers and so add variety to the discussion. He could only endorse what they had said. He was at one with Mr. Fraser with regard to the division and grouping of cases. The bad results so often seen after operation twenty years ago were due to the fact that no attempt was made at that time to differentiate between local and general disease. It was

essential to recognize the local form and to realize that it might remain local for many years. He had a patient in which the disease had been present for forty years. It subsided for a time and then became active. The results of operation in these cases were very encouraging. With regard to general infection he did not consider that simultaneous enlargement of groups of glands—for instance, in the groin and the axilla—necessarily indicated a blood infection, but the disease was of a different type from cervical tuberculosis. We should not be too much influenced by pathological changes in the treatment of tuberculous glands. It was sometimes necessary to open and deal with an abscess. When there were a great number of glands with an abscess it was his practice to treat the abscess first and then remove the glands.

As regards the age of the patient it was his opinion that the majority of cases became infected very early in life, usually in the first year. The tubercle bacillus was seldom found in the tonsil in older children, but was present in a large proportion of the younger cases. He liked to operate in early life, even in children under 1 year of age. The operation was much easier to carry out, although there was a slightly greater risk.

Infection from milk was the chief cause of cervical tuberculosis. The disease was very prevalent in Newcastle, but had become much rarer in London. Local conditions certainly affected its incidence.

Evidence that tuberculous glands could be cured by means other than operation was very slender. The tubercle bacilli did not die, although the glands might become very much smaller. Their presence could be demonstrated years after the original infection. Could the disease be cured by surgical means? He thought that the after-history of a series of his cases showed that it could. It was true that his series was not a very large one, but it was notoriously difficult to follow up patients for periods of years. He had 83 cases which he had examined from five to eighteen years after operation. Of the 83 traced, 51 were quite well and 15 had one or two slightly enlarged glands, generally on the side opposite to that on which the operation had been done. Of the remainder, some had died of intercurrent disease and a few had contracted some other form of tuberculosis. He advocated operation in as early a stage as possible. There would then be very little scarring. In late cases a poor cosmetic effect was often unavoidable.

Mr. ALEXANDER MITCHELL (Aberdeen) congratulated Mr. Fraser on his paper. In Aberdeen there were a large number of cases of cervical gland tuberculosis. He thought the milk was responsible. In London the milk came from large dairies. Smaller places were supplied by small dairies where the cows were not regularly inspected. Mr. Fraser had laid emphasis on sterilization of milk as a preventive of tuberculosis, but some children did not thrive on sterilized milk. A better procedure would be to eliminate tuberculosis from the cows. The Government should have power to deal with tuberculous cattle. At present the tuberculin test to which cattle for export were subject militated against the eradication of the disease. A well-bred animal which reacted to the test and could not be exported was not destroyed but was sold in this country and was used for breeding, thereby disseminating the disease further. A large percentage of cases was associated with diseased tonsils and adenoids. Owing to the systematic removal of unhealthy tonsils which had followed the medical inspection of schools the incidence of tuberculous glands had been diminished considerably. In treating cases he attended first to any focus of infection and put it right if possible. He then exposed the patient to sunlight as far as possible for two or three weeks. If by then the glands had not subsided he operated. As a rule he removed the glands in one stage. All cases could be cured by complete dissection of the diseased glands, but the question was, Could any cases be cured by operation other than dissection? Curotting was a much less serious operation and left a smaller scar; in a few suitable cases he thought it was to be preferred. He did not agree with Mr. Fraser that dissection was inadvisable after curotting had been done. The operation might be more difficult, but where curotting had failed the patient was often not well until dissection had been carried out. The distinction between a blood and lymphatic infection might be true in theory, but in practice it was difficult to draw a hard and fast line between the two groups. In late cases many glands were enlarged, and it might be impossible to say where the disease had started.

Dr. HUGH THURSFIELD (London) said that he saw comparatively few cases of tuberculosis of cervical glands in London. They generally went to the surgeons. He thought that only when the cervical glands had infected the mediastinum did they hand the patient over. He wished to protest against the dangerous doctrine of bovine tuberculosis. He admitted that the bovine bacillus was responsible for many cases, but some were human. By too much insistence on the bovine source the human cases might be overlooked. There were ample opportunities among the poor for direct infection. He noted a clinical difference between the human and bovine cases. There were some children who had a small shotty type of gland, and in whom the disease pursued a malignant course. He thought that this type was more likely to be caused by the human bacillus. The infection spread to the mediastinum and to other organs. In infants it rapidly became generalized. Generalized tuberculosis associated with meningitis in infants of 2, 3, or 4 years, which had begun with cervical tuberculosis, was generally due to the human bacillus. It was interesting clinically to note that when the original illness was cervical the child had nearly always been in contact with a case of human tuberculosis. He was therefore loath to consider cervical tuberculosis as usually bovine. It was true, however, that London milk was a blend derived from many cows, and that tubercle bacilli were therefore likely to be scattered in many samples.

Mr. A. MACLENNAN (Glasgow) said that cervical tuberculosis was very prevalent in Glasgow. Early operation was not possible as a rule because there was not room in the Hospital for Sick Children to admit any but the severe cases. Government interference was urgently called for to deal with tuberculous cattle. The way in which milk was treated in all its stages on the way to the consumer was disgraceful. Under present conditions it was impossible to keep it from being anything but a culture medium. He gave an instance in point. When milk was sent by rail it was the carter's business to see that it was in proper condition when it arrived. The speaker had himself seen the carter plunge a grimy hand into each can and stir the milk round in order to ascertain this. The consumer when he received it usually treated it but little better. Cases of cervical tuberculosis generally began as a mixed infection. A case was brought with acute swelling of the neck. This subsided, but not altogether. Then, when resistance became lowered, as by an attack of measles, the glands would swell again. Tonsillitis or rhinitis was often the first trouble. The pyogenic organisms acted as carriers, and paved the way for the tubercle bacillus. It was impossible to make rules of correct procedure in treatment. Each individual case had to be treated on its merits. In the first place, the diagnosis had to be considered. It was not easy to distinguish blood infections from those that were purely lymphatic. Once caseation had occurred the infection would never disappear. He did not approve of a ray treatment. Operation should be performed in the majority of cases. The formation of an abscess was no contraindication.

[He then showed a series of lantern slides illustrating various types of cases and the effect of treatment.]

Mr. L. A. PARRY (Brighton) said that he thought that the prophylactic treatment of tuberculous cervical glands was very important. If the milk supply could be guaranteed free from tubercle, if the tonsils and adenoids of children could be treated, either by operation or otherwise, and if the teeth of children could have proper attention, then tuberculous cervical glands would almost disappear. He held the view that the majority of cases were of bovine infection and due to tuberculous milk rather than of human origin. Ten per cent. of all milk supplied in London contained living tubercle bacilli. The treatment, apart from general hygienic management, which was very important, in his opinion should be removal of any gland directly it was diagnosed definitely as tuberculous. He believed that all inflamed glands were potentially tuberculous. If a gland remained enlarged a month after any source of infection was removed—for example, large tonsils and adenoids, septic teeth, impetigo, etc.—then that gland was tuberculous and should be at once removed. Operation in the early stage was much simpler and much more certain than in a late stage, in which operation was sometimes very difficult.

Dr. A. A. WARDEN (Paris) pointed out that all the speakers had treated the subject exclusively from the surgical point of view, whereas he considered that Rollier of Leysin and

Sir Henry Gauvain had shown conclusively that tuberculous disease of cervical glands was not a surgical affection and could be treated, in a large proportion of cases, on the general principles of heliotherapy. The problem was a social and economic one, and until tuberculous milk was banished treatment of the condition would be futile.

Mr. H. N. FLETCHER (Brighton) said that he thought no part of Mr. Fraser's paper was more valuable than that in which he insisted that, for some time, tuberculous disease of glands in the neck was a primary and local infection which should, whenever possible, be extirpated before it had the chance of spreading elsewhere. The last speaker had opposed operation, but had offered them nothing in its place except suggesting the adoption of the sunlight and open-air methods of Rollier and Gauvain. Heaven knew how much all of them longed for facilities such as theirs, but in most places there was no money to provide them at the present time.

As an old house-surgeon of Sir Harold Stiles, he was brought up in the faith of early and thorough excision of glands and had practised it for some years. Then for a time he had tried tuberculin injections and, if the glands broke down, aspiration, or incision, scraping, and sewing up where possible. The results of this were variable, and he determined to keep careful records of them, and did so for eighteen months. They were rather startling, and though the number was small (only 31 cases) they were worth recording, as we learnt more from comparative failure than from success. One case had the glands removed at an early stage. Of the other 30, every one broke down and supplicated sooner or later. Some came up for the first time with abscesses already formed, either under or superficial to the deep fascia; others broke down while under observation. In all cases aspirated the pus was submitted to culture, and in none were any complicating septic organisms found.

Aspiration.—Seventeen cases were repeatedly aspirated—in 6 there was eventually complete disappearance of all gland substance, and they were regarded as cured; 11 could not be so regarded in that there were some hard gland remains, which in 5 cases gave trouble subsequently.

Incision and Scraping.—Of 9 cases treated in this way, 1 was cured—that is, no remains; 8 had remains, 6 of which erupted later. The remaining 4 cases appeared for the first time with sinuses, 2 of which resulted in natural cure through discharge, and 2 had gland remains.

Of 26 cases, therefore, treated by aspiration or by scraping, only 7 were completely cured, and 11 of the incomplete cures caused further trouble within a few months.

This experience had sent him right back with renewed faith in early excision.

Aspiration certainly had its place in our methods of treatment, but it could never be wholly satisfactory. In not a few cases the caseating products were too thick to pass through even the largest needle. In other cases breaking down took place so rapidly that even frequent aspiration could not keep up with it. Again, it was a painful process which small patients dreaded. When it left hard remains it certainly gave a chance of fibrosis and perhaps cure, but there was often further breaking down later.

Until we possessed some more certain method of cure, such as, possibly, a more potent method of giving vaccines, he felt strongly that we should stick to early excision as the treatment of choice, reserving for aspiration and scraping those cases in which abscess formation has already occurred.

It was only fair to define what he meant by "early excision." There was the difficulty of deciding whether swollen glands were tuberculous or not. A sudden onset, rapid swelling, with some tenderness, were generally regarded as indicating a septic rather than a tuberculous origin. This was true of many cases, but it was surprising how many undoubtedly tuberculous glands start in this way also. If after due attention to tonsils and adenoid tissue, bad teeth, or otitis media the glands did not subside in two months, he thought they should be excised. In all cases he advised a six months' course of tuberculin in addition to general hygiene to raise the resistance of the patient.

Miss HERZFELD (Edinburgh), speaking as a disciple of Sir Harold Stiles and Mr. Fraser, said that she had investigated recently a hundred cases operated on by her in the surgical out-patient department of the Edinburgh Royal Hospital for Sick Children. With regard to the family history, 6 per cent. gave a history of tuberculosis; only 2 per

cont. of phthisis. This was in favour of bovine infection. The after history showed that one case had developed abdominal tuberculosis one year after operation; there had been no other complications. There had been one recurrence and two cases had developed glands on the opposite side of the neck. Out of 340 seen in two years 48 per cent. were apparently cured without operation. She did not use tuberculin or x rays.

Dr. MACKENZIE (Manchuria) said that there was no bovine tuberculosis in Manchuria because the people did not drink milk. Infants who were not breast-fed generally died. They were given the same diet as their parents. Human tuberculosis was very prevalent. The population lived in huts with mud floors on which they expectorated freely, and nearly every dwelling was infected with tubercle. The cases of cervical tuberculosis that came to her hospital were generally girls in their teens with advanced disease. They came then because they had reached the marriageable age and had begun to trouble about their appearance. Cases in boys were less common, probably because they led a more outdoor life.

Dr. D. SMITH thought that surgeons did not always see the first stage of cervical tuberculosis. This stage might not be tuberculous at all. The glands were primarily enlarged as the result of tonsillitis. He had removed and examined the tonsils in many of these cases and had found a streptococcal and sometimes a mixed infection. The tuberculous infection followed on this. With regard to operative measures, he had found aspiration of single glands, followed by injection of ether or other antiseptic, successful in 45 per cent. of cases where it had been tried. The infection ceased after six to ten injections. He did not believe in x ray treatment.

SCOLIOSIS.*

BY

ALEX. MacLENNAN, M.B., C.M.,

Visiting Surgeon, Royal Hospital for Sick Children; Barclay Lecturer in the University of Glasgow on the Surgical Diseases of Children and Orthopaedics.

INTRODUCTION.

THE fascination of scoliosis is certainly not financial; personally I have become involved in the treatment because numerous cases have been sent to me from the educational clinic, and I have found that the disease has presented many problems more or less knotty. As a class I have found the children so afflicted perhaps more attractive than, say, those infected by the tubercle bacillus. In the hospital we have been forced to limit the number of tuberculous inmates as so long a time of residence is required before achieving any results. That this is a very cogent reason for selection is shown by the fact that though I have nearly 100 beds at my disposal there are usually about 200 on the waiting list.

To an audience such as this I need not refer to the history of the disease nor to its incidence, but I shall at once proceed to the consideration of the etiology.

The various ostensible causes may be referred to under the following heads:

1. *Heredity*.—Many instances of scoliosis have been observed in members of one family. This does not refer to cases which are rightly described as congenital, but to those which develop during childhood, and which are unassociated with malformation of the osseous spine. That scoliosis should occur in the consanguineous is only to be expected if the variation from the normal be due to an error in growth.

2. *Osseous Defects*.—An inevitable scoliosis results from certain malformations of the spine. The well-known deformity shown in Fig. 1 illustrates the typical wedge-shaped vertebra. Figs. 2, 3, 4 illustrate similar and more complicated cases of the same type. This class may or may not be associated with cervical rib, fused ribs, elevated or diminutive scapula, spina bifida, etc. These cases approach more nearly to what might be termed a lateral curvature than do the acquired forms. These cases are somewhat rare, and do not account for the very common type of scoliosis. A congenital scoliosis indistinguishable from the prevalent type is occasionally met with. It is of course merely the result of the same cause operating at an earlier age than usual. Such irregularity in growth may similarly result in a

congenital lordosis. These uncommon cases lend support to the view that the accidental circumstances of school life have little or nothing to do with the genesis of a scoliosis.

3. *Rickets*.—This city has a somewhat unenviable reputation for want of uniformity in the human frame, hence a bias in favour of rickets being implicated in scoliosis might be expected. However, in my experience rickets and scoliosis are not frequently associated, unless we include all boy

Fixation apparatus.

irregularities in growth as having such a source. Many of the deformities are considered to be due to the so-called late rickets. If, however, the disease be considered as due to late rickets it does not advance the problem very far, for this condition itself requires elucidation, and there is no consensus of opinion as to what really late rickets is. Ordinary rickets is a disease which affects the very young, while scoliosis develops in late childhood. Rickets does not show such a predilection for the female sex as does scoliosis. When rickets attacks the spine the curvature is usually posterior and is to a large extent reducible. When the spine becomes warped in this disease it is usually late in making its appearance and is often the result, apparently at least, of inequality in the length of the legs. This causes the pelvis to tilt, with a resulting compensatory scoliosis especially noticeable in the

FIG. 6.—R. S. Fully extended. Rotation of the lumbar vertebrae still persisting. Antero-posterior view.

lumbar region. At first in rickets the bones are soft, but in scoliosis they are not so.

4. *Tuberculosis*.—When the spine is affected it is seldom that a lateral curvature is produced, and it does not concern us at present.

5. *Fracture, tumours, and osteo-arthritis* may be merely mentioned as causative factors in scoliosis.

6. *Paralysis*.—Syringomyelia, Friedreich's ataxia, hemiplegia, and spastic paraplegia may be the cause of scoliosis, but are sufficiently rare to warrant their exclusion from further consideration.

Infantile paralysis is a fertile source of scoliosis and it furnishes many examples. It must therefore be admitted that a defect located in the muscular system may be the forerunner of a spinal curvature, but such cases differ materially from the ordinary type. The curvature develops late in the course of the paralysis and it remains for a long time more or less reducible by extension. (Figs. 5, 6, 7, 8.)

* A demonstration given at the Annual Meeting in Glasgow of the British Medical Association.

7. *Muscular weakness* is a fertile source of kyphosis, but it seldom is the cause of a scoliosis.

8. *Muscular spasm* used to be considered an important factor in the production of a scoliosis.

Guerin¹ introduced deep section of the prominent muscles and induced even the conservatives of this country to try the plan, but it did not find any lasting favour.

9. The scoliosis complicating a *wry-neck* not due to a congenital malformation is secondary and compensatory (Fig. 9).

FIG. 7.

FIG. 9.

FIG. 9.—M. K., aged 15. X-ray tracing illustrating amount of scoliosis present in torticollis.

The cure of the wry-neck causes the disappearance of the curvature of the spine.

10. *Postural*.—A less definite theory implicating the nervous system has been introduced by Bankart in a couple of articles entitled "Postural or so-called static deformities."² In the section relating to scoliosis it is stated that "postural scoliosis originates as a functional nervous disorder." I have yet to come across a case which could be described as postural.

11. *Empyema* occasionally is the beginning of a spinal deviation, but it is surprising how the spine even in a delicate fragile child withstands the collapse of one side of the thorax without manifest deflection. In empyema the deflection tends towards the sound side (Fig. 10).

12. Scoliosis results to a slight degree only because of *inequality in the length of the legs*. Where the inequality is due to rickets the spine may partake of the disease, in which case the scoliosis is caused by the rickets. Apart from this such curvature occurs late and advances only sufficiently to

FIG. 10.

be compensatory. I have recently come across a case of congenital dislocation of the hip associated with scoliosis. The short leg did not, however, prevent the curvature being as shown in the figure, opposite to what was to be expected (Fig. 11). If a short leg caused a scoliosis it should have a marked influence in correcting a scoliosis developing in the opposite direction.

13. *Gravity*.—No doubt scoliosis is at least partly due to the upright position of mankind—for example, the production of scoliosis in paralysis. Its influence is, however, corrected during the periods of repose in the recumbent position. On the other hand, the influence of gravity must exert stresses and strains which tend to make the spine absolutely straight. In any case the effects of gravity apply to everyone, yet

scoliosis is, after all, a comparatively rare lesion. Its more common effect is to produce kyphosis and it takes years to do it. The prolonged assumption of the horizontal position has not resulted in the cure of the deformity.

Notwithstanding the multiplicity of theories scoliosis still remains more or less of a mystery. That rickets may be a cause is undoubted, but this does not explain how rickets works in such a direction; indeed, rickets itself requires explanation. We trace the defect far enough back if we determine that the error is one of growth, and understand its exact mechanism. We may theorize about the effect on growth of the endocrine glands, the vasomotor system, etc., but to understand the mechanics of the trouble is sufficient at present.

The view I wish to bring before you is that practically all cases of scoliosis are due to inequality of growth between the posterior part of the spine and that part composed of the bodies. It consists in an error of balance between the posterior and the anterior columns, not one due to a lateral inequality of growth. This makes a very great difference in the pathology and treatment of the condition. If it is remembered that the essential element in scoliosis is a

FIG. 13.

FIG. 13.—Diagram of model to show two columns of corks, one having a column A. Both columns are equal (illustrated). If both columns are to resume the straight aspect, column A must be lengthened. The elongated A can only retain relationship with B by convoluting.

FIG. 14.

FIG. 14.—Miss B., aged 23. Mid-dorsal scoliosis. Lateral view showing obliteration of normal dorsal kyphosis.

FIG. 15.

FIG. 15.—Miss B. Lumbar curvature increased; individual vertebrae elongated.

rotation of the vertebrae and not a curvature we may understand how great must be the dynamic force causing the deformity at its onset.

The spine is more or less a rigid structure; it is in no sense, even in delicate girls, what has been indeed, the more "willowy" the less will develop (Fig. 12). A small amount of movement is allowed in various directions, but the range is strictly limited. In the dorsal region the range is more limited than any other part, yet it is just in this region that the deformity takes place. It must take place because any excess of growth in one section over another cannot here be accommodated, as it can be in the more mobile sections. If the spine were willowy, as in quadrupeds, a little irregularity in growth would not result in obvious deviation. As a support the spine may be divided into two parts, an anterior column composed of the vertebral bodies and discs, while the laminae and spinous processes together form a posterior column. If the anterior column does not keep pace with the posterior it becomes a mechanical necessity for curvature to result. Kyphosis results from inefficient anterior growth, while lordosis results from anterior overgrowth. A very considerable amplitude is allowed in the lumbar region and in the cervical, but little is possible in the dorsal. Such inequality in growth in this part of the spine must find another plan for taking up the inequality. In scoliosis the overgrowing anterior column does this piece of accommodation by assuming a wavy configuration; rotation of the individual vertebrae is an essential concomitant. Reference to Fig. 13 will better explain the mechanism.

1. This view explains how the curvature of the anterior column made by the bodies of the vertebrae takes place before any apparent curvature is noticeable when viewed from

to back, and that it is always greater than any such visible curvature. This, of course, implies a rotation of the bodies—an almost impossible contortion of the parts unless we regard it as of a gradual production by growth.

2. It explains the simultaneous production of the so-called secondary curvatures, which are not secondary at all. Such curvatures are usually double, may be treble, or even present five undulations.

3. It explains the early flattening of the back or local lordosis accompanying the elongation of the anterior column. The obtrusive posterior curvature is more apparent than all; it is largely due to projection of the angles of the ribs. When such lordosis is marked the disproportion in length of the two columns is probably great; hence this feature is regarded as unfavourable. The normal posterior curvature, of course, obliterated early in development of the malady. Fig. 14 illustrates this sign very well. Fig. 15, on the other hand, shows the excessive lumbar curve and the elongated bodies.

4. The difficulty of reduction by almost any means becomes so easily understood.

5. It gives an explanation of the slow development of scoliosis in the congenital wedge-shaped vertebra.

6. It also may be used to support the Abbott plan of correcting the curvature in flexion rather than extension.

7. It further renders comprehensible how, when the normal spine has been artificially deformed by the experimental application of the Abbott jacket, it straightens itself spontaneously if not interfered with.

The signs and symptoms of scoliosis are too well known to refer to, but I might accentuate the importance of the x-ray examination. The skiagram prevents us from taking too optimistic a view of our treatment.

The only anatomical alteration which might be referred to is the change in the shape of the bodies and the development of the wedge shape. This occurs late in the course of the disease. One need not look to the intervertebral discs for the key to the mystery of scoliosis, but to the epiphyses of the bodies. The discs are inert, passive indeed; they compress during the day to the extent of $1/2$ to $3/4$ in. Forming as they do one-fifth of the entire column, this means only small condensation in each.

The treatment of the malady is the important and the most difficult section of the subject. Adams' sums up the matter in the following sentence: "All the resources of medical and mechanical science are required either to cure or arrest the progress of the affliction." I fear that this opinion of Adams is shared by many; it certainly has been mine, and it has induced me to persevere with the forcible methods of correction—the Abbott jacket and operation.

The operation which I have been practising for some years is done in selected cases. It is carried out as follows:

A 4-inch incision is made over the convexity of the curve. It is placed just external to the tips of the transverse processes. The dissection will vary according to the locality, but the muscles are split rather than cut. The posterior nerve branches are conserved as far as possible, as their division is liable to be followed by the development of a hyperaesthetic area just where subsequently sustained pressure is required to be made.

Two, or at most three, ribs are resected from their angles to their articulations with the vertebrae. The pleura is very liable to injury, and the wound retractors should be wrapped in gauze to minimize this risk. The tissues over the vertebral bodies are raised from the lateral fossa, avoiding injury to vessels or nerves. One or two sets of intercostal vessels may require ligation, but in most cases it is possible to avoid ligaturing any vessel. On account of the deflection of the vertebral bodies towards the convexity they are much more accessible than would be expected. The body of the vertebrae forming the centre of the curve is excavated and the same is done to the vertebra above and below though not so severely. The vertebral substance is nibbled or cut away so made the spine is forcibly in order to reduce the curve, to ascertain if any takes place. Even when the

curvature is large it is surprising how little the spine gives way. The wound is closed in layers without drainage.

A plaster-of-Paris jacket is applied with the spine flexed laterally as much as possible. The patient may get out of bed within the week, as it is desired to collapse the cavity in the bodies as soon as possible. With the gap in the anterior column it might be expected that a gibbus would form, but this has not been my experience. The posterior column, composed of the laminae, etc., is so strong that the spine does not collapse before the operative gap in the bodies fills up solidly.

The sutures are removed in three weeks if unabsorbable, and a new jacket applied again in extreme lateral flexion. From subsequent x-ray examination it has become plain that the curvature has not been immediately obliterated to the extent expected (for the reason given above), so that the operation resolved itself into an arthrodesis and obliteration of epiphyses. In the cases so

operated upon I have been more than satisfied that the risk involved has been compensated for by the improvement. Having obliterated the growth of more than one vertebral epiphysis the distortion will tend to reduce as the posterior part of the spine increases in length. In one case it was not convenient to perform this operation, so a graft was applied to the lateral aspect of the spine with moderate success.

In the after-treatment I have found the felt padding employed in the Abbott treatment very irksome to the patient, besides being prone to displacement and in hospital patients to become the breeding ground for vermin. To obviate this I have inserted rubber bags in the two situations where padding will be required, and these may be inflated to the desired amount. The pressure so exercised has been much less objectionable to the patients.

As a routine I now treat all cases by the Abbott jacket, and in those which are advanced, or which show little tendency for the deformity to stabilize, I operate, but not after the age of 15, as little growth is to be expected subsequently. A jacket, either plaster-of-Paris, celluloid, or made by the instrument maker, should be worn for some years. The x-ray examination of the spine will provide data on which to proceed as regards further treatment. In some cases a jacket should be permanently applied. A slight reduction of the curvature, visible on the skiagram, means a great step towards cure; it implies a reversal of the forces which originally warped the spine.

I need hardly refer to the prognosis more than to say that the subjects of scoliosis who are neglected, or left uncured or not improved, do not live long. This also is my apology for applying a somewhat severe and risky operation to alleviate the condition.

SPLENECTOMY, APPENDECTOMY, AND CAESAREAN SECTION IN THE SAME PATIENT.

IN view of the large number of patients who resign themselves to a life of semi-invalidism after a single major abdominal operation, the following case may be of interest.

Mrs. R., married eight years, had the spleen, weighing 12 oz., removed at the age of 31, for acholuric jaundice; at 32 the appendix was removed for acute appendicitis; at 33 she was delivered at term of her first child, a female, weighing just over 6 lb., by Caesarean section for generally contracted pelvis, after twenty-four hours' labour. After the last operation there was some trouble with a stitch abscess or infected haematoma, but both mother and child are doing well, and leaving hospital in good health.

ADRENALINE: TOXIC DOSE.

A LADY, who suffered from periodic attacks of asthma, was in the habit of administering hypodermically to herself two or three times a day, on the advice of some consultant, 10 minims of adrenaline solution during an attack.

An attack supervened as she was about to return home from the north of England, on a very troublesome journey. She administered 20 minims, and repeated it every two hours (with very little relief) for six doses. On her arrival home she had administered 120 minims of an undiluted solution of adrenaline (Parke, Davis, and Co.) in ten hours.

I was called to see her, and found her condition alarming. She was intensely pale, collapsed, pulse almost indistinguishable, and she had blurred vision, auria, and intense thirst. Her condition improved quickly on the administration of amyl nitrite, and when later an administration of morphine and atropine was permissible to alleviate the asthma, after two doses at intervals of four hours she had regained the normal.

I am unable to find any evidence of so much adrenaline being taken in so short a time. I have very little doubt that another dose or two would have proved fatal.

Reports of Societies.

FORTY-FIVE YEARS OF MEDICAL PROGRESS.

At a meeting of the Medical Section of the Royal Society of Medicine on October 24th Dr. G. Newton Pitt, the President, delivered his address from the chair.

Dr. Newton Pitt chose for his subject the advances in medicine since he became a medical student forty-five years ago. The increased knowledge of disease, with consequent improvement in treatment, had been due, in the first place, to bacteriology; secondly, to the revolution in surgery; thirdly, to the establishment of laboratories, with experts in microscopy and biochemistry; and fourthly, to much more minute attention to physical signs. The discovery of the organisms of enteric, tuberculosis, malaria, diphtheria, and syphilis had in each case been momentous; likewise the discovery of serums and vaccines. The use of diphtheritic antitoxin had reduced the mortality in the larger hospitals from 40 to 7 per cent. The revolution in surgery appeared a wonderful thing to those who remembered the conditions obtaining forty-five years ago, when only the pioneers were using the carbolic spray, and when operating coats were invariably dirty, and gloves, caps, and sterile overalls and dressings unknown. With the coming of aseptic surgery it was possible to deal with abdominal lesions which were not amenable to medical treatment, and at the present time the abdomen possibly was opened too frequently. The majority of cases of gastric and duodenal ulcer would heal under medical treatment, but in about one-third of the cases, owing to perforation, adhesions, fibrosis, or other mechanical conditions interfering with peristalsis, relief could be obtained only by surgical methods. With modern aids to diagnosis the existence of an ulcer could be detected much more easily and certainly than before, so that it might be expected that deaths due to ulceration would have diminished; but Guy's Hospital records showed the total mortality due to gastric and duodenal ulcers to be greater than it was forty years ago; the number of fatal cases of peritonitis also was on the increase. It was clear from a study of the figures that during the period under review there had been a steady increase in the number of cases in which there was some infective process in the alimentary canal. The incidence of appendicitis was very remarkable. The hospital records showed for some years before 1889 an average mortality of about three deaths in two years. For the last fifteen years the average had been twenty a year. Previous to 1889 fewer than twenty cases were admitted to the hospital in a year; by 1899 the number admitted had increased to 100 or more, and now the number was 400 or 500. The inflammation also was much less acute in the early days. In only one out of eleven cases in 1888 was the appendix removed, and yet there were no deaths. It would be almost out of the question to take a series of eleven cases at the present time and have them all recover, with the removal of the appendix in only one instance. Another notable advance was represented by the information now to be obtained from the chemical examination of secretions, excretions, and blood. The staining and counting of the blood cells was so familiar that people did not always remember that it did not come into general use until 1888, while the Wassermann reaction was first used only in 1906, and the estimation of urea and sugar in the blood was of still more recent date. Important help was now afforded through improved instruments for internal observation, especially x-ray apparatus. With the use of x-rays and the bismuth meal the alimentary canal could be mapped out from end to end, and it seemed possible now, with the injection of gas, to outline radioscopically the solid viscera. But the introduction of very powerful x-ray apparatus would prove a serious danger to the habitual user unless more stringent precautions were enforced. In all these examinations team work should be encouraged, but it was important that the clinician should have the last word.

Dr. Newton Pitt went on to speak of the change of view which had taken place with regard to some familiar diseases. It was now well understood that tuberculous infection was very frequent among town populations, and that recovery was the rule and not the exception. Forty-five years ago the possibility of recovery from phthisis was hardly credited, and heredity was looked upon as the dominating factor. The most striking example of diminution of virulence in disease was afforded by scarlet fever, the mortality of which had

greatly diminished, although the disease came in periodic waves, so that the incidence in 1921 was more than treble what it was in 1920. Formerly the mortality from scarlet fever was as high as 30 per cent.; by 1900 it had fallen to 5 per cent., and now it was less than 1 per cent. In Paris for many years this disease had been looked upon as a very trivial one, and it was tending to be so regarded in England. During the period between 1880 and 1920 the mortality from measles, whooping-cough, and phthisis was reduced by more than half. Improved methods of treatment had reduced to negligible proportions small-pox, anthrax, glanders, hydrophobia, and tetanus. Another very striking fall was the diminution in mortality from liver and gall-bladder disease, a diminution which must be attributed rather to surgery than to medicine. Influenza had been a perennial scourge of recent years, and with this was probably associated in some way the increase in appendicitis. Pneumonia, cancer, hemiplegia, heart disease, and digestive disorders showed no diminution in mortality and no material improvement.

In medical custom one great change to be noted was the reduction in the amount of stimulants used in hospitals. When he first joined the hospital the ordinary diet for the hospital patient included two or more pints of beer or stout, and in all serious illnesses spirits were prescribed. Alcohol was now given only in special cases, and with great moderation. One advantage which the medical man of to-day had over the man of a generation ago was the present largeness and accessibility of medical literature, particularly in the form of abstracts. In what direction was medicine likely to advance? There was no doubt that Sir James Mackenzie was right in insisting that the most urgent need was a fuller knowledge of the habits and slight deviations from health which led to disease later. The mortality from renal, vascular, and most of the nervous diseases, also from pneumonia and bronchitis, had not been appreciably diminished during the last fifty years. There was much to learn as to the infections which ultimately produced arteriosclerosis. Gout, rheumatoid arthritis, and other degenerative lesions might conceivably be prevented in the future; they could not be cured in the present.

Dr. HECTOR MACKENZIE, in proposing a vote of thanks, said that he himself was able to look back upon the same length of time as Dr. Newton Pitt. He could endorse what he had said about the incidence of appendicitis. Years ago at St. Thomas's this was regarded as an extremely rare condition, but after the operative era commenced they began to find how common a thing it was. Nevertheless, he was not so sure that actual perforation of the vermiform appendix had become much more common than it was before. With regard to tuberculosis, he thought that those went a little too far who assumed a universal infection of the race with tubercle. It might be true, but he did not think it had been absolutely proved.

Dr. BERNARD MYERS, in seconding, said that years ago he worked under the late John Duncan, the first to use spray for the disinfection of the air, and he had often heard him describe the conditions in those early days when the carbolic spray made everybody sneeze and feel unwell. The speaker went on to say that in one district where he had occasion to go to study the death returns for the year the thing that had struck him was the want of diagnosis. Such entries as "convulsions" and "heart disease" were useless from the point of view of statistics. It was possible that in many respects the clinician had become very much more accurate in diagnosis. He was able to confirm his diagnosis nowadays through the help rendered to him by the biochemist and others doing special work, though the final diagnosis must be made by the clinician himself. It was well to preserve a sense of balance with regard to methods of treatment. Many people, for instance, were advised, on account of some septic condition, to have all their teeth removed, and having submitted to this they became very much worse than they were before. With regard to tonsils, he still did not understand why it was that some surgeons were taking out practically all tonsils. There were cases where the tonsils must be removed, but there were also many in which this was not essential. It was necessary to observe carefully and come to a calm judgement on all these clinical matters.

The Eradication of Glanders and Anthrax.

Major-General Sir JOHN MOORE, F.R.C.V.S., read a paper on the eradication of glanders and anthrax in men and animals. In no instance, he said, could the progress of veterinary science be so clearly demonstrated as in the

eradication of glanders, thanks to the use of mallein as a diagnostic agent. Last year only three outbreaks of glanders were recorded, and this year only two, whereas in the years from 1900 to 1906 the outbreaks each year numbered more than 1,000. The extinction in human practice depended, of course, upon the extinction of the disease in animals. With regard to anthrax the position was much less satisfactory. Despite present knowledge and measures of control, anthrax continued to prevail, and the situation in respect to its eradication seemed wellnigh hopeless. He gave some interesting examples of how soil infection was the chief factor in the incidence in India, though this was not so prominent a factor at home. An analysis of cases of anthrax amongst animals in Great Britain showed that infection resulted mainly from imported foodstuffs. Here again a reduction of the incidence in human beings was dependent upon the completeness of the control of the disease in animals. He criticized the inadequacy of control in India, and the need for improvements in the civil-veterinary department there.

ECONOMICS AND TUBERCULOSIS.

A MEETING of the Section of Epidemiology and State Medicine of the Royal Society of Medicine was held on October 27th, the President, Colonel R. J. REECE, C.B., M.D., in the chair. Dr. R. J. EWART read a paper on economics and tuberculosis. Dr. Ewart, having referred to the eugenic hypothesis that selection had been a principal factor in the decline of mortality from tuberculosis, suggested that a simpler explanation could be given. He displayed diagrams showing a close parallelism between the changes in real wages and the changes in the rate of mortality from phthisis. No similar correspondence with fluctuations of percentages employed was found, and he suggested that this was because the aid rendered by the Poor Law sufficed to maintain the state of public health during periods of economic depression without interfering with the economic life of the community. Dr. Ewart then remarked that it was common ground that the response of the somatic cell to infection by the tubercle bacillus depended upon the former's state of nutrition; he suggested that the response of the germinal cell needed consideration. He referred to the evidence published by various inquirers tending to show a higher male to female ratio at birth under unfavourable conditions. He thought that similar effects were operative when the offspring of early and late parturients were compared. Passing to the application of the hypothesis to the problem of tuberculosis, Dr. Ewart emphasized the fallacies inherent in the application of statistical methods to the scanty available data, but thought there was *prima facie* evidence that, due allowance being made for the age at death of the parent, children born in later life broke down earlier than those born to younger parents, and had a more variable mean age at breakdown. The inference was that bad conditions of pre-natal environment led to the production of a unit of enhanced susceptibility and that the post-natal continuance of such unfavourable conditions led to destruction. He remarked that the fall in the birth rate was associated with a considerable change in the birth-age distribution and that, on that account, the mean susceptibility of the population was still decreasing. Dr. Ewart thought caution was needed in testing the theory on the basis of current rates of mortality. In his opinion a slight apparent increase of mortality from phthisis should be expected in the next two years, not because of the wave of unemployment but because the rate of the years following the war had been abnormally low, owing to the bad conditions of the war period having hastened the fatal issue in a proportion of cases. Any increase in 1922-24 was to be regarded as a return to the normal rate of decline. Dr. Ewart's general impression was optimistic; the somatic cell had responded to the improvement of food supply, the reproductive cell was beginning to respond, thus the level of immunity would be raised and a further decline of phthisis mortality produced.

In the discussion which followed, Dr. MAJOR GREENWOOD said that Dr. Ewart's paper consisted of two parts—the first, which dealt with the general correlation between economic prosperity and the prevalence of fatal tuberculosis, displayed in an interesting fashion a relation which he (Dr. Greenwood) supposed everyone appreciated in a more or less vague way. But it certainly did not follow from Dr. Ewart's curves that antituberculosis measures other than improving national nutrition were unimportant. He also failed to follow Dr. Ewart's argument that the machinery of the Poor Law was

so efficient that the standard of nutrition did not deteriorate when the percentage of unemployed persons increased. The second part of Dr. Ewart's paper propounded the interesting hypothesis that the powers of resistance to tuberculosis of children born to parents in the latter part of the fertile period were less than those of children born to young parents. Since the decline of fertility of the last generation affected fertility at later ages more than fertility at younger ages, Dr. Ewart's suggestion was, apparently, that we had here another factor likely to continue to diminish the death rate from tuberculosis. The suggestion was interesting, but a partial coefficient of correlation of 0.26 was a shaky foundation upon which to build, particularly when, for technical reasons, the probable error was difficult to interpret. From a statistical point of view, he did not feel able to draw any conclusions and could only regard Dr. Ewart's evidence as suggestive.

Dr. S. VERR PEARSON thought that Dr. Ewart's paper reinforced the arguments used by Dr. Baskett in various communications to the BRITISH MEDICAL JOURNAL. Dr. Pearson was of opinion that the economic element in etiology was of great importance, and that in recent public health actions it had not always been given the weight it deserved.

Dr. A. K. CHALMERS commented on the fact that in Scotland the death rate from tuberculosis began to fall about 1874, after the importation of foreign meat had begun to be considerable, and the decline was associated with increasing use of meat. He thought that it might be more than a coincidence that the great decline in child mortality began in or about 1903, when the first generation to feel the effects of an improving food supply were becoming of reproductive age.

Dr. COURTS said that no one would doubt the immense importance of the nutritional factor in the etiology of tuberculosis, dramatic examples of which were afforded by the war-time experience of Poland and Austria. He shared Dr. Greenwood's scepticism as to the interpretation of the curve of unemployment and as to the sufficiency of the Poor Law to account for the lack of apparent correlation. The complete statistics of 1922 were not available, but the first quarter of that year showed an increase in mortality from tuberculosis over the first quarter of 1921. All would agree with Dr. Pearson's contention that if taxation for public health measures lowered real wages it was bad for the public health, but it was not clear that this had happened. Again, it was not the policy of the central authority that tuberculosis officers should devote the major part of their time to treatment; it was intended that they should regard preventive work as their chief aim. He thought intercol statistical comparisons more likely to be of value in the measurement of the effect of various measures than massed data, and deprecated the attribution of the total national effect to any one factor.

Dr. HAMEN said that two of the speakers had warned members not to speak disrespectfully of the tubercle bacillus; for his part he regarded the bacillus with deep respect, but must call attention to the fact that Dr. Balstrode had been a true prophet in his forecast of what would happen to the rate of decline of tuberculosis.

Dr. WILLIAMSON said it was becoming fashionable to attribute the decline of tuberculosis to everything but anti-tuberculosis measures, but active workers were still convinced that infection played a predominant part. In war time imported labour corps suffered severely, although their economic condition had been improved; in Sweden, although the economic position had presumably improved, the death rate from tuberculosis had not declined.

Dr. J. C. McVAIL could not suppress a doubt whether the money saved by cutting down health services would really be spent upon food. There were such things as cinemas and football matches. On a certain occasion it was suggested that a supply of spikewards might have been sold for a great sum and the money given to the poor, but still the doubt crept in whether it would have been given to the poor. He thought there must be a certain proportion of waste in every kind of expenditure, and that the educative value of public health efforts in themselves housing, feeding, and general sanitation were in themselves enough justification for what had been done. The greatest sanitarian of Scotland, the late Dr. J. B. Russell, had been a great educator.

Dr. R. J. EWART, in replying, said that Dr. Baskett had done pioneer work on the relation between economics and disease, and that he himself had followed a similar line, but with rather different data. He agreed that the evidence on

the influence of parental age was no more than suggestive. The sample (200 observations) was small; it was not a random sample of the general population, and the regression was not linear.

THE NOTIFICATION OF INFECTIOUS DISEASES.

At a meeting of the Harveian Society on October 26th, held at Paddington Town Hall, a discussion took place on the notification of infectious diseases. Sir WILLIAM WILCOX, President of the Society, was in the chair.

Dr. REGINALD DUDFIELD (Medical Officer of Health for Paddington) introduced the subject with a short history of notification. It was in response to the urgent demands of medical officers of health that notification of infectious diseases was introduced. The appointment of such officers was a consequence of the report of the Royal Commission on the health of towns (1845), and the first officer was appointed in 1847 by the city of Liverpool. In London the placing of medical officers in charge of various parishes and districts led to the formation of what was now known as the Society of Medical Officers of Health—an organization which played no small part in bringing about notification. The efforts of the British Medical Association in the same direction should also be noted. The most important function of a medical officer of health was the prevention of disease, but the discharge of such a function presupposed a knowledge of the presence of disease in a community. In London it became at once the practice for the Registrar-General to forward every week to the medical officers of health copies of the entries in the registers of deaths made by the district registrars. The analysis of the returns was carried out in different ways. In 1855 Sir Benjamin Ward Richardson began the tabulations which he published in the *Journal of Public Health*, and in 1855 the British Medical Association began the collection and publication of statistics of sickness and mortality. The various attempts to collect and analyse the returns, however, were generally a failure, owing in most cases to loss of interest on the part of the persons charged with supplying the basic facts. Appeals were made to the Government to set up a national system for the registration of disease. It was uncertain at what period the demand for registration of disease was replaced by a demand for the notification of infectious disease, but the latter demand was resisted by the Government until the utility of notification had been demonstrated by local experiment. Such notification was first brought into operation at Huddersfield in 1876, and at Bolton in the following year. At the end of 1881 more than a score of cities and towns, all of them except one (Reading) in the north of England, had introduced notification in their areas, in each instance by a private Act of Parliament. Then came the well-known Notification Act of 1889, whose provisions were at once adopted by nearly a thousand sanitary authorities. In London the earliest proposal to extend notification appeared to be in a circular letter from the Local Government Board in 1894, following cholera outbreaks of the two previous years.

Dr. Dudfield then submitted a list of diseases to be notified in the county of London:

Anthrax	Erysipelas	Polio-encephalitis
Cerebro-spinal fever	Glanders	(acute)
Cholera	Hydrophobia	Polio-myelitis (acute)
Continued fever	Malaria	Relapsing fever
Diphtheria	Membranous croup	Scarlet fever
Dysentery	Ophthalmia neonatorum	Small-pox
Encephalitis lethargica	Plague	Trench fever
Enteric (typhoid)	Pneumonia	Tuberculosis (all forms)
	Puerperal fever	Typhus fever

Measles, first cases only, had to be notified in seven boroughs, and all cases in two; German measles, first cases in four boroughs, and all cases in one (Paddington); whooping-cough, first cases in one borough (Battersea), and all cases in three boroughs; and diarrhoea, zymotic enteritis, in three boroughs among young children only, in two boroughs during the summer months, but with no age limit, and in one borough (Woolwich) all cases throughout the year. In Greater London, including the counties of Essex, Hertfordshire, Kent, Middlesex, and Surrey, the list just given held good, except that anthrax, glanders, and hydrophobia were only notifiable in certain areas, chicken-pox was notifiable in ten areas, measles and whooping-cough (generally first cases only) in a few areas, and epidemic diarrhoea in Beckenham during the summer months.

Speaking from his own practical experience, which covered the period since the Act of 1889, Dr. Dudfield said that he found notification of the diseases laid down originally in that Act to be very complete, with the exception of puerperal fever. Once or twice a year deaths from that disease came to his knowledge without previous notification. All cases of sepsis ought to be notified whether after delivery at term or after miscarriage or abortion. With regard to pneumonias, approximately one-sixth of the deaths in 1921 due to primary lobar pneumonia represented cases which had not been notified. The notification of diseases not in the original Act was improving every year, except in the case of tuberculosis. Compulsory notification of tuberculosis was preceded by voluntary notification in a number of sanitary areas. In 1911 voluntary notification was in use in the areas of 321 authorities, in one of which (Carlisle) it covered all forms of the disease, and not the pulmonary alone, as in the other areas. In many areas it did not prove successful, and compulsory notification was introduced, the first area to adopt it being Sheffield in 1903. The notification of tuberculosis left much to be desired. From 1914 to 1918, 20.5 per cent. of the deaths due to pulmonary tuberculosis were in cases which had not been notified, and of the deaths due to other forms of tuberculosis 51 per cent. had not been notified. That this was not due to war conditions was shown by the figures for a later period, 1919-21, when the percentage of non-notified cases among the deaths was 24.1 and 56.2 in the two categories respectively. The notification of pulmonary tuberculosis was not popular with the public, nor with some members of the medical profession. He was inclined to think it would be advantageous to notify tuberculosis as suspect only in the first instance, with a view to admission to a hospital for observation. The doubt in the public mind with regard to a possible error in labelling would thus be removed.

A Demand for Revision of the List of Notifiable Diseases.

Dr. CHARLES BUTTAR said that Dr. Dudfield had treated the subject so seriously that he was nervous about reading the ribald remarks he had prepared. His contention was, however, that notification was a nuisance to doctors and an expense to ratepayers. Notifiable diseases were piled up without any clear consideration of the reasons for making them notifiable; diseases no longer or never worth notifying were kept on the list, and complications were introduced by allowing various bodies to make orders for notification and withdraw and reintroduce them. Originally there were eleven diseases notifiable in the county of London; now there were about thirty. It would be interesting to know how many medical officers could recite the thirty and give the reasons why each was notifiable. Some of them were notifiable in one area and not in another, or at one time and not at another. It was an annoyance to be called upon to notify rubella in Paddington and not in Kensington, whooping-cough in Willesden and not in Paddington, while the in-and-out antics of chicken-pox were exasperating. Nothing but real tangible benefit could justify such anomalies, and the annoyance was not soothed by payment of a fee, whether half a crown a case for whooping-cough, or a shilling a dozen or a gross for measles, as with families and institutions during the war. The original object of the Acts, which was to control the disease with a view to its extirpation, had been modified by subsidiary propositions, such as the benefit of the individual sufferer and the advancement of knowledge. He urged that the utmost care should be exercised in the selection of notifiable diseases; the object of notification in each case should be definable and reasonably attainable, and the decision as to the suitability for notification would be best arrived at after preliminary discussion between health officers and medical practitioners.

Dr. Buttarr went on to challenge certain inclusions in Dr. Dudfield's list. Two items in that list—continued fever and membranous croup—he regarded as non-existent as notifiable diseases. The only condition in which he could imagine the existence of membranous croup was in a scalded throat, and if this was so he doubted its infectivity. Erysipelas and relapsing fever, he thought, had ceased to be worth notifying. Was it really necessary to fill in a certificate and for the public to pay half a crown because some old lady had scratched a streptococcus into her skin? As for relapsing fever, it would be interesting to know when and where this was last notified. Puerperal fever was insufficiently defined, and therefore unsatisfactory for notification. Medical officers ought to know exactly what they meant by the term and produce definite evidence that their efforts had led to diminution or control.

He could not imagine any real usefulness in the notification of puerperal fever except in the case of septicaemia. In diphtheria and scarlet fever the possibility of control was somewhat doubtful; at all events, the results of notification had not been startling. He was inclined to the view that nowadays the notification of scarlet fever was of little practical use. Diseases which did seem to be controllable were small-pox, cholera, typhus, and typhoid, and he submitted that the cloven diseases originally notifiable should be cut down to these four, together with diphtheria. With regard to additional diseases, anthrax, glanders, and hydrophobia, at present only notifiable under local orders in a number of districts, might be made permanently notifiable throughout the country as in the case of plague. It was conceivable that a good case might be made out for adding malaria to the list of diseases in which there was reasonable certainty of obtaining control; and encephalitis lethargica and cerebro-spinal fever might be retained, not because health officers were likely to be of the slightest use in controlling them, but because the conditions were comparatively new: they were dangerous, and something would be gained scientifically by submitting them to the opinion of experts. Whooping-cough, measles, and German measles should be removed from the list at once. If the gain to the community was worth the trouble and expense involved in notification, then notification should be extended to the whole country, and not appertain to here one area and there another. Diseases in which notification was not worth while were trench fever, dysentery, and acute primary and acute influenzal pneumonia. There was no reasonable hope of extirpating the pneumonias, however much they were notified. In tuberculosis notification had proved more useless than in other diseases. In the notification of tuberculosis there were many fallacies which reduced its value from the scientific point of view. Notification assisted very little in early diagnosis, and its objects could be met equally well by trusting the doctors. In conclusion, he urged that the Ministry of Health might wisely consult on this matter with the Royal Colleges and the British Medical Association, and the local medical officer of health might usefully seek the opinions of the practitioners in his area.

Dr. W. H. HAZEN (Medical Officer of Health, London County Council) agreed with Dr. Buttar as to the lack of any particular value in the notification of measles, German measles, and whooping-cough. But in the case of some other diseases in the list he could not go as far. He would be very reluctant to see the notification of scarlet fever, puerperal fever, and ophthalmia neonatorum disappear. A great deal of value attached to the notification of the latter two, and with regard to scarlet fever he thought that hospital isolation was very useful indeed. When the mortality of scarlet fever to-day was compared with what it was in his own young days an enormous improvement was self-evident. A hundred years ago scarlet fever was a more terrible plague than it was in his own youth. He believed that the isolation of scarlet-fever cases in hospitals had a great deal to do with its present mildness. He would be sorry also to see relapsing fever disappear from the list. It was apt to prevail in association with typhus, and the amount of relapsing fever and typhus which had been in Europe since the war was not realized in this country. A case could be made out also for keeping plague and anthrax in the list of notifiable diseases, and he confessed that he had "a sneaking sort of regard for erysipelas." At the same time there was too much tendency to regard notification as good in itself, whereas it was only of benefit if it led to some practical issue. As to statistical value, the statistics furnished by notification were apt to be misleading. The Metropolitan Asylums Board in its annual report stated that in recent years the margin of error in the notification of typhoid fever had been something like 40 per cent. Notification might under-represent or over-represent the true incidence. In a case of doubt, for example, he was inclined to think that the proper course was to notify. From the statistical point of view, however, notification had the advantage that it enabled a tabulation of the case mortality to be made. It enabled one to test any supposed variation of disease in type, and he reminded the meeting of the remark of Murchison that when people talked about change of type in disease, what they were dealing with was not change of type, but mental revolutions in the minds of practitioners. On the whole he thought that notification ought to be treated with a good deal of respect, though it was not by any means the last word to be said about the diagnosis of disease.

Dr. T. CARNWATH (Ministry of Health) said that his chief

interest in notification was from the point of view of public health administration, though the statistical aspect was also important. The diseases notifiable in London could be grouped under two main headings: those notifiable under Section 55 of the Public Health (London) Act, and those notifiable under order of the Local Government Board or the Ministry of Health. The list given in Section 55 could be extended, and was in fact extended, to measles, whooping-cough, and other diseases in certain boroughs, but that was a local matter over which the Ministry had very little control. Certain pains and penalties attached to the persons notified under this section, and therefore it was found desirable later, instead of using the section, to make the diseases notifiable by order because then the exact measures to be taken could be prescribed. If tuberculosis had been made notifiable under Section 55 all sorts of pains and penalties would attach to the notified person which might make it impossible for him to follow his profession. When the notification of disease was first introduced it was looked upon as an essential measure in the control of disease. The activities of public health officers resulted in the elimination of such diseases as typhoid and typhus, in which the environmental factor was principally concerned, but in the case of diseases in which the personal factor was concerned less had been done to affect incidence, though in the case of one disease in this group—small-pox—the state of affairs had been altered, chiefly by vaccination. Dr. Hamer appeared to think that measures of notification and hospital isolation had affected the mortality from scarlet fever. That was open to question, however, because from the statistics of some foreign countries where isolation and other customary measures were not adopted to the same extent the same decline in mortality from the disease was noticeable. When the local authority was notified of a case of scarlet fever it was mainly for the purpose of treatment, and once that conception was adopted one got local authorities, as at Willesden, asking whether there were not other diseases which could be treated to better purpose with the accommodation available than scarlet fever, at least in the mild form. One of the main purposes of the statistical department should be to study the trend of disease and the factors which influenced it, and to discover which of these factors was amenable to control. Personally he would like to see not only infectious diseases notified, but occasionally, and for other purposes, other diseases such as chlorosis. It had been hoped that the record cards of insurance practitioners would furnish particulars, but the suggestion had not been received with favour. It was natural on the part of a Government paying hundreds of thousands of pounds on the treatment of disease to inquire what diseases were most responsible for the mass of invalidity. From a cursory inquiry it seemed that about one-seventh of the money was paid out in respect of rheumatism, and the Ministry had started a special inquiry to find out what rheumatism counted. Until it was known what diseases were chiefly responsible the Ministry would be undecided as to where to step in to help practitioners.

Dr. C. SANDERS (Medical Officer of Health, West Ham) said that he had some sympathy with the views put forward by Dr. Buttar. Notification, however, was introduced not for the purpose of keeping a check upon such physicians as Dr. Buttar, but to assist practitioners working among great industrial populations, where there was frequently poverty and carelessness or ignorance of hygiene. In his own district the notification of scarlet fever served a very useful purpose, because from the moment of notification certain administrative measures went forward automatically, and these were of the greatest value in stopping the spread in schools. The gravamen of the charge brought by Dr. Buttar arose out of the difficulties which practitioners encountered when the disease was notifiable on one side of the street and not on the other (the two sides being in different boroughs). Arrangements ought to be made for notification to be universal throughout the country. He could not conceive that the local affairs in one district could be so different from those in a contiguous district as to make notification necessary in the one and not in the other. He would welcome more notification rather than less.

Dr. HUBERT C. PHILLIPS said that when notification was compulsory in one borough and not in another the public was very quick to seize upon the anomaly. He advocated an order from the Ministry which would be irrespective of local opinion.

Sir WILLIAM WILCOX, in closing the discussion, confessed that he would have been "ploughed" had he been required

to name all the diseases notifiable in London according to the list which Dr. Dudfield had brought forward. He did not agree with Dr. Dudfield in pressing for the notification of all suspected cases of tuberculosis. He had seen so many people put down as suffering from tuberculosis whom they were not so at all that he felt that the notification of suspected cases would have a detrimental effect psychologically upon many people who would be proved afterwards not to have the disease. He would be rigid in the diagnosis of tuberculosis before notification. Not many months ago he saw a man of strong build and appearance, with no clinical signs of tuberculosis whatever, who had been sent to a sanatorium on the strength of an x-ray picture of his chest, and even the radiological finding was not confirmed by a second observer. A great deal of harm could be done by reckless notification of tuberculosis. The War Office had a rule that no case should be notified as tuberculous unless tubercle bacilli were found. Dr. Buttar's trenchant contribution had been most welcome and illuminating, though he could not agree with all his criticisms. He believed that relapsing fever should be retained on the list. In the war he saw a large number of cases of typhus and relapsing fever in Mesopotamia and Egypt; the two diseases always came in association, one after the other. It was true that many medical men had never seen relapsing fever in this country, but it was well known to their predecessors at the London fever hospitals, and they were aware of its differentiation from typhus and the association of the two diseases. He thought that scarlet fever also should be retained on the list. He had an opportunity of seeing cases of scarlet fever at the fever hospital, and he was impressed by the number of cases which came in from a case which had been missed. Dr. Carnwath had referred to the desirability of notification of some other diseases. Chlorosis, which he had mentioned, was almost unknown in the out-patient departments of London hospitals, and another disease almost unknown there was typical gout. There was no doubt that rheumatism—to use a loose term—was very much on the increase; probably it was the commonest disease at the present time. There was no doubt that complaints which he looked upon as streptococcal toxæmias occurred in people who were incapable of resistance owing to bad home conditions. It was noteworthy that both a medical officer of health (Dr. Sanders) and a general practitioner (Dr. Phillips) had said that they would welcome universal notification. It seemed absurd that diseases should be notifiable on one side of the street and not on the other, and he imagined that if it came to a legal issue it would be almost out of the question to secure a conviction against a practitioner for failing to notify, because the practitioner could hardly be expected to say to which of two contiguous areas the patient belonged.

Dr. DUDFIELD, in a brief reply, said that with regard to tuberculosis his suggestion was only that all cases of tuberculosis should be notified in the first instance as suspect, and the final notification should only be made after the patient had been under hospital observation. Time was an essential factor in the treatment of tuberculosis, and the provision of observation beds was being widely extended. As for Dr. Buttar, it had to be remembered that Dr. Buttar was an exceptional man: notification was not introduced for the purpose of controlling or assisting such as Dr. Buttar. The class of people with whom the speaker had to deal as notified persons was very different from the class of people among whom Dr. Buttar practised.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

THE second meeting of the session of the Royal Medico-Chirurgical Society of Glasgow was held on October 20th, when a number of interesting papers were read and cases illustrating them were demonstrated.

Early Opacities in the Senile Lens.

Mr. IANIS POLLOCK read a paper on the treatment of early opacities in the senile lens, and demonstrated six cases. He referred to a long list of many surgeons who had attempted at different times, and in different countries, to carry this out with the aid of potassium iodide and other alkaline salts.

Nearly all ophthalmic surgeons had seen at times traumatic cataract absorbed in part; and a certain number of cases of the spontaneous absorption of senile cataract were on record, so that it was undoubtedly possible for opacities to disappear in the human lens in comparatively rare cases, but the

numerous cases which had been reported, especially during the last twenty years, showed that the alkaline treatment of senile cataract had been used successfully, and that the results were not due to spontaneous absorption nor to clearing of the vitreous or fundus opacities. He further considered that as early treatment was now recommended in general medicine as the proper treatment for every type of disease, therefore the early medical treatment of cataract should be tried in all cases, and if possible the patient should not be told of the existence of the cataract, so as to prevent worry becoming an element in the case.

Asymmetry of the Upper Limbs.

Dr. MATTHEW WHITE made a short communication on a case of asymmetry of the upper limbs, and showed the patient. On examination after an injury to the right shoulder asymmetry of the arms was noted, the left apparently being the normal one and corresponding to the general development of the body. At the first examination the rest of the body appeared to be symmetrical, but ten months later there was scoliosis with tilting of the head, asymmetry of the face, and on several occasions inequality of the pupils. Sensation appeared to be normal in the affected arm; no difference in power as shown by dynamometric measurements was noticed, although the right hand tired more quickly than the left. The skin of the forearm and hand, as compared with the left side, was coarse and thickened. Cuts and abrasions on the right arm healed slowly and became purulent. The blood pressure and temperature were identical on both sides. Skiagrams of the bones of the hands and arms showed greater density and thickening on the right side. There was nothing of note in the region of the sella turcica.

Treatment of Rectal Prolapse in Children.

Dr. LEONARD FINDLAY and Dr. J. D. GALBRAITH made a short communication on the treatment of rectal prolapse in children. The method referred to, that of Professor D'Espine of Geneva, consists in the introduction of a small amount of absolute alcohol into the loose areolar tissue surrounding the rectum. The operation is simple in technique, efficient in results, and apparently devoid of all danger. The speakers reported the results in 41 children. In 7 cases prolapse had been in existence for less than one month; in 10 cases it had been present for more than a year. In two cases the operation had to be repeated once, and in one case twice, but in all the other examples only one treatment was necessary to obtain a cure. Cure was obtained in 90 per cent. of cases.

Polydactylism of the Foot.

Mr. G. H. EDINGTON and Dr. W. B. PRIMROSE made a communication on a rare case of polydactylism of the foot. The subject of this communication was a male infant aged 4 months. The abnormality consisted of three supernumerary toes occupying the left between the hallux and the normal second toe of the left foot. The supernumerary digits were not at all in the same plane, one being dorsal and two displaced towards the plantar surface of the foot. These last were webbed in half their length and capable of active movements. The dorsal digit was not actually mobile. A skiagram showed three supernumerary metatarsal bones, two of which belonged to the plantar toes, and the third, which was imperfect, to the dorsal toe. A wedge of tissue, including the abnormal structures, was removed from the dorsum and the result showed little difference between the two feet.

Dr. W. B. PRIMROSE said that the wedge of tissue removed by Mr. Edington showed upon dissection that the dorsal rudimentary toe had only two phalanges and a very imperfect metatarsal bone which had no tarsal articulation. It was bound to the lateral side of the adjacent toe in a loose manner by fibrous tissue instead of by ligament. The other toes were much better developed. Their metatarsals had tarsal articulations, but they possessed deformed cartilaginous phalanges. These two toes showed the normal arrangement of flexor and extensor tendons, while the dorsal rudimentary toe only possessed an extensor tendon. There were, in addition, two dorsal interosseous muscles, but one of them had the appearance of being formed by the fusion of two adjacent interosseous muscles. The greater part of the blood supply of these toes was apparently derived from the first dorsal metatarsal artery by two arcuate vessels which cross the two medial metatarsal bones dorsally. This suggested a relationship of all these toes with the hallux, which was of teratological significance. The digital cutaneous nerves were relatively normal.

BRITISH ORTHOPAEDIC ASSOCIATION.

THE annual meeting of the British Orthopaedic Association was held in London on October 20th and 21st, under the presidency of Sir ROBERT JONES. About seventy members and visitors attended the meeting.

On the morning of October 20th, at the Royal Society of Medicine, papers were read on: "Tumours of tendons and tendon sheaths," by Mr. ST. J. D. BUXTON; "Results of tendon transplantation for intrinsic hand paralysis (Ney operation)," by Mr. J. G. JOINSTON; "Kohler's disease of the tarsal scaphoid," by Mr. E. S. BURNETT; "Infantile paralysis," by Dr. LEVICK; "Some complications of supracondylar fractures," by Mr. W. R. BRISTOW; "Two cases illustrating the longitudinal growth of scar tissue, and a case illustrating the reaction of bone to pressure," by Mr. D. MCCRAE AITKEN; "Types of tubercle bacilli in surgical tuberculosis," by Dr. G. R. GIBBLETT; "Coxa plana," by Professor MURK JENSEN; "An operation for the relief of flexion contractures in the forearm," by Mr. C. MAX PAGE. In the afternoon the Association met at the Royal National Orthopaedic Hospital. Demonstrations were given by Mr. JACKSON CLARKE, illustrating the use of spinal supports; Mr. LAMING EVANS, the results of Whitman's operation for talipes calcaneocervus; Mr. R. C. ELSLAW, fixation of the tendo Achillis for talipes calcaneus; Mr. BANKART, congenital talipes equinovarus treated by silk fixation after correction of the deformity; Mr. TRETHOWAN, bone grafting for malunited Pott's fracture, bone grafting for non-union of radius and clavicle, bone grafting to reconstruct acetabulum in congenital dislocation of the hip, arthroplasty of hips and knee, tendon transplantation for calcaneus, tendon transplantation (various), flat-feet, congenital club-foot, osteotomy for genu recurvatum, bilateral pes cavus; Mr. ROGER JONES, the results of an operation for hallux valgus and rigidus, and some tendon transplants. Each of the surgeons afterwards performed an operation of the class which was illustrated by the cases he had previously shown.

On October 21st the Association met at the Royal College of Surgeons, where Sir ARTHUR KEITH gave a short demonstration, including a discussion of the osteology of a cannula. Mr. LAWTON KNAGGS showed specimens and discussed the pathology of serous periostitis, osteitis fibrosa, osteomalacia, and leontiasis ossea. Dr. THURSFIELD and Mr. FURNACE briefly discussed conditions of generalized bone deformities in children. The specimens illustrating these several conditions were demonstrated in the Museum.

The dinner of the Association, held on Friday, October 20th, was attended by seventy-two members and guests.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

The first meeting of the session of the West Kent Medico-Chirurgical Society was held on October 13th at the Miller Hospital, Greenwich, when Dr. E. W. FAHNER occupied the chair, and the annual reports were read and approved and officers for the ensuing session were elected. Dr. W. H. PAYNE was elected president and took the chair, and a number of clinical cases were then shown.

Mr. C. A. JOLL showed a patient, a young woman whom he had operated on for a myeloma which had destroyed the head of the humerus. A free-bone graft taken from the upper two-thirds of the fibula was inserted, which persisted and functioned, as was shown by the x-ray plate. He also showed the case of a boy with enlarged glands of the neck, which were tuberculous with a septic element. Dr. H. PITCHARD showed a young woman with asites suffering from mitral disease, which developed eighteen years ago after acute rheumatism. She had been tapped twenty-four times in twenty-one months, the quantity of fluid varying from 14½ to 20 pints. Dr. A. S. WOODWARD showed a case of asites in a man who had been tapped seventeen times since November 15th, 1921. He had albuminuria, aortic regurgitation, and hypertrophy of the heart; 18½ pints was the average quantity of fluid removed. He also showed a boy suffering from Graves's disease, with tachycardia; he had been treated by x-rays, bromides, and a fat-free diet, along with an ounce of cod-liver oil daily. An x-ray plate of a gastric ulcer taken by Dr. BUCHAN was shown. Dr. H. CONST showed, on behalf of Mr. H. DAVIES, a case of pseudo-elephantiasis, which did not extend below the ankle; a wedge-shaped mass of tissue had been excised.

Reviews.

SMELL AND TASTE.

PROFESSOR G. H. PARKER of Harvard University has contributed a valuable monograph on *Smell, Taste, and Allied Senses in the Vertebrates* to a series of monographs upon experimental biology.¹ As the editors point out, the rapid increase of specialization and the adoption in biology of the methods of the exact sciences have rendered it impracticable for one author to cover satisfactorily the whole field; these monographs, of which seven have now appeared, stand as an indication of the great advance which the sciences of experimental biology and general physiology have made in recent years.

Hitherto the sense organs concerned with smell and taste have on the whole received less attention than the others, and yet biologically they are of very great importance. As Professor Parker, whose researches on these subjects are well known, deals with smell and taste, and certain other associated though less familiar senses, from the standpoint of their functional interrelation and genetic connexion, this monograph will prove of interest and value to a very wide circle of readers.

Each chapter is prefaced by a table of its contents, and at the end of each is a very complete bibliography. Another good feature of the book is that Professor Parker has provided a critical review of the evolution of knowledge of various aspects of the subject and a clear statement of the present position, together with suggestions as to the lines upon which future research may most profitably be conducted.

A lucid account is given of what has been ascertained with regard to the common chemical factor in substances which arouse the same taste, but, as the author states, although it seems beyond reasonable doubt that the sour taste is in some way dependent upon hydrogen ions, the problem of how these ions become effective has still to be solved. The peculiar chemical feature whereby the other tastes excite their effect is more illusive and less understood, but an excellent summary of the present position is placed before the reader. The author forcibly expresses the opinion that in gustation three and probably four well-defined senses may be distinguished, since their functional difference is beyond doubt, although structurally they have not yet been separated. To the reviewer structural distinction at the periphery does not appear to be a necessity; further knowledge of the representation of the gustatory sense in the central nervous system is of much more urgent and vital importance.

The consideration of the work which has been undertaken with regard to the physiology of olfaction is extremely thorough and complete, and, as an authoritative opinion is expressed on the value of all the more important investigations, this section must prove most helpful to everyone interested in this special sense. The work of Zwaardemaker with his olfactometer, by which he was able to measure olfactory stimuli, together with the modification of van Dam, and the more recent olfactometer of Allison and Klitz are discussed. A full statement of the attempts to classify odours is presented and the difficulties which have been experienced in correlating the chemical formulae of substances which give the same smell are explained. The author admits that recent attempts to connect odour and chemical constitution are fragmentary, yet he inclines to the belief that this line of research promises to provide a solution of the problems as yet unsettled. In the light of this prophecy it is of interest to mention an effort by Heynix to put the olfactory sense on a physical basis; his researches, however, have been published since the completion of the monograph under review. Heynix has made use of Castelli's theory of resonance in vision, and demonstrates a correspondence between the size of the pigment granules in the olfactory mucous membrane and the wave-length which odorous substances emit. Professor Parker's masterly treatment of the subject is likely to attract more workers to this fascinating yet difficult problem. The concluding chapter on the interrelation of the chemical senses may be read with much enjoyment; it is full of information and suggestion; and must provide a stimulus to all readers of this most attractive monograph.

¹ *Smell, Taste, and Allied Senses in the Vertebrates*. By G. H. Parker, Sc.D. Monographs on Experimental Biology. Philadelphia and London: J. B. Lippincott Co. 1922. (Post 8vo, pp. 192; 37 figures. 10s. 6d. net.)

ENDOCRINOLOGY AND METABOLISM.

THE five large volumes entitled *Endocrinology and Metabolism*,¹ edited by Dr. LEWELLYS F. BARKER, with Professor R. G. HOSKINS and Dr. HERMAN O. MOSENTHAL as associate editors in endocrinology and metabolism respectively, contain in their 4,770 pages a series of monographs; the fifth and least bulky of the volumes is entirely devoted to the bibliography and general index of the first four volumes, the first two of which deal with endocrinology and the other two with metabolism. The ninety-eight contributors, with the exception of Professor Swale Vincent, who recently returned to this country, all hail from the United States and Canada, and are fairly equally divided between the two subjects; they include the well-known authorities G. N. Stewart, W. B. Cannon, A. S. Warthin, W. Timme, O. Klotz, D. Marine, F. M. Pottenger, and C. E. de M. Sajous on the ductless glands, and Graham Lusk, D. van Slyke, C. Voegtlin, P. B. Hawk, J. C. Aub, E. Du Bois, A. I. Kendall, E. C. McCollum, G. R. Minot, J. H. Pratt, W. T. Longcope, R. Woodyatt, and F. W. Penbody on metabolism. A wise and critical judgement is thus assured on two subjects about which, as the editor remarks in his prefatory note, "much speculative nonsense has been written of late."

The two volumes on endocrinology begin with a section containing articles on the general aspects of the subject. Dr. Fielding H. Garrison's history of the endocrine doctrine is especially interesting and is illustrated by fourteen portraits of pioneers, beginning with Théophile de Borden (1722-76), a physician at the court of Louis XV, who, Max Neuburger contends, anticipated the modern conception of the internal secretions.

In an introductory article Dr. Hoskins criticizes current nomenclature, such as hormones and autocoids, but without any enthusiasm or, indeed, real suggestions for reform, except one to the effect that the names of special substances should not be finally decided until they have been isolated and chemically identified. He does not find any convincing evidence that endocrine factors play a significant part in the onset of senility; and in conclusion utters a caution against the premature construction of hypotheses about the mechanism of the internal secretions.

In his discussion of the hormone factors in growth and development Dr. E. Ullenhuth expresses the opinion that the thymus is not concerned in the control of growth and development in spite of the rather widespread belief to the contrary; in a subsequent article Dr. Hoskins adopts a similar negative attitude with regard to its possession of a true endocrine function. Professor J. T. Halsey of New Orleans gives a comprehensive review of organotherapy in some seventy pages, leaving the subject of ovarian therapy to Dr. E. Novak. The difficult subject of the relations between the endocrine organs and the autonomic nervous system, or how the vegetative nerves influence the endocrine glands and how the chemical substances produced by these glands influence the visceral nerves, is clearly handled by Dr. F. M. Pottenger, who wholeheartedly accepts the conception of vagotonia and sympathicotonia; the associate editor, however, has inserted a moderating footnote to the effect that, while the fundamental conception seems valuable, the want of constancy in the manifestations of these two states detracts from its clinical utility.

After these six articles of a general character the thyroid, parathyroid, and pituitary glands are considered in minute detail, several writers contributing their quota to each subject; thus Dr. E. V. Cowdry writes on the anatomy, embryology, and histology of all these glands. Although it is impossible even to mention all the contributors reference should be made to Professor Swale Vincent's article on the physiology of the thyroid, Dr. Campbell Howard's scholarly account of hyperthyroidism, including exophthalmic goitre, for which he has collected twenty additional synonyms, to Dr. Lewellys Barker's clinical syndromes due to disorders of the parathyroid glands, mainly tetany of course, which occupies more than a hundred pages, and to Dr. Harvey G. Beck's account of dystrophia adiposogenitalis.

The second volume contains the remainder of the subject of endocrinology in seventeen sections, of which that on the suprarenals and the chromaffin system, occupying 300 pages,

is much the largest. Dr. Cowdry describes the anatomy, embryology, comparative anatomy, and histology of the suprarenals, and also of the other glands of internal secretion considered in the volume. Writing on the significance of the suprarenal glands in relation to the vital processes, Professor G. N. Stewart of Cleveland, who has given much time to the investigation of these problems, critically discusses the control of suprarenal secretion; faulty methods have, he says, been responsible for misleading views which, like the elaborato hypothesis of the reciprocal relations of the endocrine glands, have been accepted too readily. Nothing, he considers, is certainly known of the supposed detoxicating function of the adrenals, or the power of neutralizing toxins produced in metabolism. In a short article on the emergency function of the suprarenal medulla Professor W. B. Cannon of Harvard considers the evidence for and against his view that adrenaline secretion is stimulated by excitement, pain, and dyspnoea, and states that as yet there is no reliable proof that any secretion of adrenaline occurs in peaceful conditions. The relation of the suprarenals to the circulation is then discussed by Dr. R. G. Hoskins, and the general pharmacology and toxicology of these glands by Professor F. A. Hartman, who is also responsible for their general physiology and experimental pathology. In the section on the male and female gonads the interstitial cells are fully discussed and figured; Professor Swale Vincent, who writes on the physiology, physiological chemistry, and experimental pathology of the female gonads, considers unsatisfactory the evidence adduced in favour of the view that the interstitial cells in the testes and in the ovary belong to the same category.

Writing on the correlation of the endocrine organs Dr. R. G. Hoskins says that the assumption that all the endocrine glands are in intimate functional relation to each other has not been demonstrated to be true, and that a diagnosis of pluriglandular syndrome is often merely camouflage for ignorance. It is therefore interesting to read what Professor Walter Timme, who in 1918 described the thymus-suprarenal-pituitary compensatory syndrome, which in another work Lewellys Barker labelled Timme's syndrome, has to say in his article on the polyglandular syndromes. While admitting that the whole subject is at present more or less confused and that the syndromes are of necessity not clearly separated from each other, he gives an account of two groups which he regards as fairly well defined: first, pluriglandular insufficiency, in which the glands affected are chiefly the thyroid, gonads, pituitary, and adrenals, and of which Claude and Gougerot's typo is described; and secondly, pluriglandular compensation, with an account of his syndrome with its four stages. He also deals with endocrine disorders associated with muscular dystrophies and expresses the opinion that calcification of the pineal gland is the underlying lesion of progressive muscular dystrophy.

The two volumes on metabolism are prefaced by Professor Graham Lusk's history of the subject from the earliest times; due attention is directed to the dietetic observations of William Stark (1740-70) and to the work of Mayon, who also died early; of Priestley, Black, Lavoisier, and others; the rise of German science, starting with Liebig (1803-73) and continued by Voit, Zuntz, and Rubner, is mentioned; reference is rightly made to recent work in France and America; and finally, "Across the water in that wonderful island called Great Britain are Hopkins, T. B. Wood, Halliburton, Cathcart, Leonard Hill, Hardy, E. H. Starling, and others, through whose unrecognized efforts the food program of their country was saved from disaster during the war."

The first section on dietary constituents and their derivatives begins with Dr. A. I. Ringer's article of seventy pages on the proteins and their derivatives, and this is succeeded by Professor Walter Jones's account of nucleic acids. Professor W. R. Bloor first classifies the fats and allied substances on the basis of their relations to the fatty acids in metabolism under the main heads of the simple, the compound, and the derived lipoids, and then proceeds to deal with the digestion and absorption of fats. In connexion with lipemia he expresses the opinion that lecithin and cholesterol are stages in metabolism through which fats may or must pass before they can be utilized. The important article on carbohydrates and their metabolism, contributed by Drs. A. I. Ringer and Emil J. Bauman, first passes in review their chemistry, classification, and nomenclature and then goes on to their digestion, the question of carbohydrate tolerance, and other aspects of metabolism. In discussing vitamins Professor Carl Voegtlin concludes that very possibly they act as catalysts in some metabolic reactions, and may also indirectly

affect nutrition by stimulating the digestive organs. The article on normal diet is from the pen of Dr. Isidor Greca-wald. Professor J. R. Murlin devotes a hundred pages and forty-five figures, many of them representing different forms of calorimeters, to the essential subject of the normal processes of energy metabolism.

In a most interesting account of bacterial metabolism, normal and abnormal, within the body Professor A. I. Kendall insists that diagnostic or morphological bacteriology must give place to dynamic or chemical bacteriology, and sets forth the principles of "bacterio-chemistry." The evolution of bacteria from saprophytic types through parasitic to pathogenic types appears to be attended by a well-marked decrease in the chemical activities of the microbes, and, generally, chemical activity seems to be incompatible

The specificity of action of the vast pathogenic for man is held to depend upon their utilization of protein for energy; they become potentially lactic acid bacilli when growing in an environment containing carbohydrates or other non-nitrogenous products, instead of forming indol and other toxins from proteins. The effects of sugars upon the intestinal flora is a subject the author has specially investigated; thus has arisen "bromatherapy," or the treatment of certain intestinal infections so as to diminish the formation of toxic bodies from protein cleavage and to render the intestinal contents acid. Among the other articles attention may be directed to Professor H. C. Barbour's detailed account of the influence of certain drugs and poisons on metabolism, to Dr. Boek's articles on the effect of transfusion, and to Dr. T. Ordway and Professor A. Knudson's description of the effects of x rays and radio-active substances.

The fourth volume deals with pathological metabolism and is divided into two sections: the first deals with general pathological metabolism, in articles on undernutrition, obesity, acidosis, oedema, anapylaxis, fever, traumatic shock, and disturbances of growth; the second consists of twenty-seven articles concerning special pathological metabolism, such as in diabetes mellitus, nephritis, gout, alkaptonuria, cystinuria, gastro-intestinal, hepatic, pancreatic, and other diseases. In his clear and authoritative account of acidosis, Dr. D. Van Slyke refers to alkalosis or uncompensated alkali excess in the blood, and accepts the view that it causes tetany; he adds, however, that it does not follow from this that all cases of tetany are due to the same cause; in a later article, when describing its metabolism, Dr. F. H. McCraddon discusses the possibility that alkalosis plays a part in the etiology of progressive muscular dystrophy. Carbohydrate acidosis is naturally that mainly considered in Dr. Van Slyke's article; it is also referred to by Dr. R. T. Woodyatt in his account of the pathological metabolism of diabetes mellitus. Van Slyke also summarizes existing knowledge on acidosis in renal disease, which is probably due to retained phosphoric acid; he admits that it has not yet been shown whether the moderate compensated alkali defect is important in accelerating the progress of the disease, and whether a patient in such a condition is benefited by measures to restore the alkali reserve. He cautiously expresses the opinion that, since the acid-base balance is obviously unstable and the compensated acidosis may become uncompensated, treatment on these lines may possibly be desirable; for this purpose an abundant fruit and vegetable diet which produces more alkali than acid is recommended.

Whatever the primary cause of oedema, whether renal insufficiency, damage of the capillaries, or disturbance of metabolic processes in the tissue cells, the problem of oedema is that of the interchange of fluid, with its dissolved and suspended substances, between the blood and the tissues, and accordingly Professor Franklin C. McLean discusses these at length; in some remarks on the treatment of oedema he describes the administration of thyroid extract in myocardial disease and chronic parenchymatous nephritis; this is recommended by Eppinger and Epstein when they advocate a diet rich in proteins and poor in fats for patients with chronic parenchymatous nephritis. Fat metabolism and the blood lipoids in nephritis are considered in the course of Dr. H. O. Moseenthal's valuable article dealing with metabolism in nephritis. Dr. Joseph H. Pratt of Boston, whose name is well known in connexion with gout, writes fully and impartially on its metabolism and gives useful summaries of the opinions held about the treatment by diet and by atophan. In an elaborate article on the important subject of the pathological metabolism of the blood and the blood-forming organs, Dr. S. Hurwitz first reviews the recent

work on blood destruction and regeneration, then discusses the metabolism in blood diseases, and finally considers the influence on metabolism exerted by senile measures, such as splenectomy, x rays, and radium, employed in the treatment of blood diseases.

It must be gratefully recognized that these volumes contain an immense store of information, contributed by authoritative writers from a country where their investigation has been widely and energetically carried on, and that the editors' labours therefore are most welcome in having thus provided us with a valuable source of reference.

DISEASES OF CHILDREN.

The Diseases of Children, Medical and Surgical, by the late Dr. HENRY ASHBY and the late Mr. G. A. WRIGHT, was a valuable and popular textbook on the subject which reached its fifth edition in 1905. A sixth edition now appears.¹ The medical chapters have been revised by Dr. Ingh T. Ashby; the revision of the surgical matter which had not been finished by Mr. G. A. Wright at the time of his death has been completed by Mr. Charles Roberts. The character and aim of the book is still well described in a paragraph of the preface of the first edition: "The original feature of this book is that it is written conjointly by a physician and a surgeon; it is hoped that it presents therefore a fairly complete account of disease in children. Though we are well aware that the book is not an exhaustive treatise we think it will be found practical, and it is at least based on experience and is not a mere compilation." The successful career of the book through several editions was the best proof of its useful and practical character, and the present edition will, we think, maintain its reputation. As to the inclusion of medical and surgical diseases in one volume, that still remains an original feature. Almost all the diseases incident to infancy and childhood are dealt with, for, besides surgical and medical conditions, the infectious fevers, affections of the ear, nose, and throat, and of the teeth, are all included. This range of subject-matter is rather that of an encyclopaedia, and it could only be compressed within the limits of a book by a concise and essentially practical treatment of the individual diseases. The new edition is of rather smaller bulk than the old, so that it retains the original character of brief and summary statement, in which the more important conditions are dealt with in a few pages, while rarer diseases are sketched in a short paragraph. That leaves little room for theories of etiology, for accounts of pathology, for references to authorities; but room is found in a praise-worthy way for the citation of a few telling and illustrative clinical records. Yet, while this severe and almost dangerous brevity is the outward mark of the book, its soul is the very large individual experience of the late authors; and its success and reliability rest upon that secure foundation. The claim in the original preface that it is not a compilation is fully justified. It is a book that may be safely commended to the busy practitioner—a brief working manual for the demands of daily practice, where within the covers of one volume he may find short but trustworthy guidance to the diagnosis and treatment of the very numerous and various conditions of disease incident to childhood. The volume is well illustrated, and, though the number of illustrations has been reduced in the new edition, many new ones have been included, and there is a good index. The revisers are to be congratulated on their success in the difficult task of bringing the new volume up to date while preserving the spirit and character of the old. We anticipate that this well-known book will continue its honourable and useful career.

The aim which Dr. L. W. HILL tells us he had before him in preparing his book on *Practical Infant Feeding*² was to produce a volume "practical without being superficial, scientific without being tiresome." On the subject of infant feeding the aim is laudable, but not easily to be attained; the subject is full of difficulties. Chemical and physiological data are copious and exact, but not as yet securely linked with the clinical data; pathology is obscure, and the whole ground is

¹ *The Diseases of Children*, by the late Henry Ashby, M.D., F.R.C.S., and the late Mr. G. A. Wright, M.B., B.S., F.R.C.S. Sixth edition. Oxford Medical Publications. Stoughton, 1922. (Demy 8vo., 24s. net.)

² *Practical Infant Feeding*, by the late Henry Ashby, M.D., F.R.C.S., and the late Mr. G. A. Wright, M.B., B.S., F.R.C.S. Sixth edition. Oxford Medical Publications. Stoughton, 1922. (Demy 8vo., 24s. net.)

By the late Henry Ashby, M.D., F.R.C.S., and the late Mr. G. A. Wright, M.B., B.S., F.R.C.S. Sixth edition. Philadelphia and London: W. B. Saunders Company. 483; 40 figures.

covered with a tangle of conflicting theories. The author devotes some preliminary chapters to the physiology and bacteriology of digestion in infancy, to the analysis of human milk, and to the rules for breast feeding. He then enters the debatable ground of artificial infant feeding. He begins by giving a short historical sketch of the various theories with their corresponding applications in treatment, dealing in succession with percentage feeding and the exact adjustment of milk mixtures advocated by Biedert, Meigs, and Rotch; with the bacteriological teaching of Escherich; with the views of Czerny on milk fat; and with the latest chemical theories of Finkelstein as to the influence of the sugar and the salts in cow's milk. Dr. Hill is unwilling to discard entirely any of these theories, contradictory though some of them may appear to be; he maintains that in each there is a precious residuum of truth, which modern practice can make use of. This is an attitude of mind favourable to the reception of truth from whatever point of the compass it may come. But it has its dangers; and this book shows signs of them, while the history of the subject abounds in instances. The attitude is facile, and those who take it are apt to be carried about by any wind of doctrine blowing now from America, and next from Central Europe. The author in his practice of artificial feeding favours a milk mixture low in protein and salts, but fairly high in sugar and fat; he obtains the result he desires by the use of gravity cream and skimmed milk. It should be said that the book does not contain any clinical records of healthy or dyspeptic infants to illustrate and prove the theories and doctrines of feeding that are discussed. This lack of clinical illustration detracts not a little from its value.

The chapter on premature infants is written by Dr. W. H. Howell; and there are chapters on diarrhoea, chronic intestinal indigestion, constipation, pyloric stenosis and spasm, rickets, scurvy, and spasiophililia.

A SYNOPSIS OF SURGERY.

The sixth edition of Hey Groves's well-known and deservedly popular *Synopsis of Surgery*² has just been published. The success which this book has attained is the result of its excellent plan, rendering it exceptionally lucid in its brief descriptions. There is no doubt that the author expended a vast amount of labour on the first edition, and he chose his authorities wisely and well. Indeed, when this book first appeared its teachings were in advance of many of the textbooks of the day. The sections on those subjects of which Hey Groves is admittedly a master have been brought up to date. But there are others that need more careful revision, and use might have been made of many of the valuable monographs which have appeared during the past few years, largely in the journal which Hey Groves himself edits. In many instances no more than a sentence would have been needed to mark a definite advance in our knowledge. More stress, for instance, might have been laid on appendicular obstruction in the etiology of acute appendicitis; and the colicky pains widespread across the abdomen which herald the onset of an acute attack are not mentioned.

In spite of some defects, the book remains a good one because its principles are sound. But we trust that more radical revision of some sections may be instituted in future editions, lest the book in time should lose the enviable position which it has held in the past.

MORBID FEARS AND COMPULSIONS.

In his volume on *Morbid Fears and Compulsions*³ Dr. H. W. Frink gives a readable and comprehensive account of the theory of psycho-analysis and its practical applications in the treatment of the psycho-neuroses. He follows closely the teaching of Freud, and expresses himself as having but little sympathy with the post-analytic schools of Adler and Jung. Beyond the fact that Dr. Frink suggests the substitution of the term "sexual" by the broader one "homophilic," the earlier chapters which deal with general principles are written on familiar lines, and thus suggest no special comments. The more recent developments of the libido theory and its appli-

cations to the psychoses are not discussed. This may be due to the fact that this book was first published in America in 1918, so that the author was at that time unacquainted with Freud's most recent views. In any case these latest developments are chiefly of interest to the advanced student of psycho-analysis, and do not conflict with the details included in this volume. Later chapters in the book are devoted to an account of cases of compulsion neurosis and of anxiety hysteria. The author explains that these cases fail to illustrate in certain particulars the theories he has discussed in earlier chapters; he points out that a completely analysed case could not have been compressed within the limits of his book, and he proposes to write a supplementary volume which will be devoted to a single case report. The last chapter is concerned with a discussion of the theory and mechanism of the psycho-analytic cure.

The volume has the advantage of an introduction by Dr. J. J. Putnam, in which he discusses what he considers to be the defects and limitations of Freud's doctrines of the human mind, his criticisms being directed more especially to the mechanistic philosophy upon which they are based. The book may be recommended to those who wish to obtain a systematic and more than elementary account of the subject with which it deals.

THE SECOND HALF OF LIFE.

*Senescence: The Last Half of Life*⁴ is the latest fruit of the full life of the well-known psychologist, G. STANLEY HALL, President of Clark University, and its publication follows his retirement from that post. It describes old age and death from many points of view, but its main object is the demonstration that intelligent and well-preserved senectitude has important social and anthropological duties in the modern world, though hitherto these have not been utilized or even recognized; thus, with the passing of sexual activity and of ambition for place and fame there comes, he says, an Indian summer of increased clarity and efficiency in intellectual work and a philosophic calm. Writing in a genial, autobiographical strain he expresses his frank conviction that the medical profession knows little of old age, that there are no gerontologists, as there are paediatrists and gynaecologists, that centenarians owe their longevity much more to their own insight than to medical care, and therefore that for the most part the old man must be his own doctor. A chapter, however, is devoted to a useful and judicious abstract of various medical men's views on the changes and treatment of old age. In a critical estimate of Metchnikoff's well-known views he praises the optimism and intention that stimulated his writings, but regards the value of sour milk as overestimated. The rejuvenating effects obtained by vasectomy by Steinach and by transplantation of the testis by Voronoff are fully described, and the author concludes that the only practical hope of relief from the hardships of senescence and of the postponement of death is that now faintly and tentatively arising and suggesting that some mitigation may be obtained by glandular implantation, or perhaps even by the injection of the secretions of endocrine glands. Dr. Stanley Hall analyses the returns he obtained from a set of questions addressed to a few score of mostly eminent and some very distinguished elders of the United States. To the question, "To what do you ascribe your long life?" the reply most often given was good heredity, and then "the preservative influence of good and temperate habits, reinforced by observation of acquaintances of early life who, by reason of less moderation, have preceded them to the cemetery."

This is an interesting volume, at least to those whose "way of life is fall'n into the sere, the yellow leaf," and has many pleasing personal touches.

THE WORKMEN'S COMPENSATION ACT.

DURING the war two Acts were passed increasing the amount of compensation payable to an injured workman under the Workmen's Compensation Act, 1906, but no other material changes were effected in the original Act. In the second edition of his book on *Medico-Legal Examinations and the Workmen's Compensation Act*⁵ Sir JOHN COLLIE has accordingly reprinted the first edition without change, and added to

¹ *Senescence: The Last Half of Life*. By G. Stanley Hall, Ph.D., LL.D. London and New York: D. Appleton and Co. 1922. (Pp. xxvii + 518. 21s.)

² *Medico-Legal Examinations and the Workmen's Compensation Act, 1906, as Amended by Subsequent Acts*. By Sir John Collie, C.M.G., M.D., J.P., Lieutenant-Colonel R.A.M.C. Second edition. London: Baillière, Tindall, and Cox. 1922. (Demy 8vo, pp. 157. 6s. net.)

³ *A Synopsis of Surgery*. By Ernest W. Hey Groves, M.D., M.Sc., F.R.C.S. Sixth edition. Bristol: John Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd.; Toronto: The Macmillan Company of Canada, Ltd. 1922. (Cr. 8vo, pp. 621; 23 figures, 13 plates. 17s. 6d. net.)

⁴ *Morbid Fears and Compulsions: Their Psychology and Psycho-analytic Treatment*. By H. W. Frink, M.D., Assistant Professor of Neurology in Cornell University Medical College. With an introduction by James J. Putnam, M.D. London: Kegan Paul, Trench, Trubner, and Co., Ltd. (Demy 8vo, pp. xxiii + 344. 21s. net.)

it some twenty-eight pages in which he has briefly considered the effect of war pensions on compensation, the employer's liability to pay compensation to a man in prison, and some recent decisions which throw light upon the fundamental intentions of the Act of 1906. This method of procedure is not entirely satisfactory, as it necessarily leaves in the new edition various statements which are now out of date or require modification—for example, the statistics given in various places nowhere relate to a year later than 1909. Further, the decisions given in what are known as the "wall" case and the "air raid" case go far, as the author points out, towards finally and clearly defining the intention and scope of the Act, and consequently now render superfluous the considerable space which Sir John Collio devoted to the discussion of these questions in the first edition.

In spite of this defect, however, the book can be cordially recommended to practitioners who are concerned with compensation cases, while medical referees under the Act will find much of interest in the author's suggestions for improving the Act.

The earlier part of the volume contains many examples of clever malingering, and accounts of the skilful methods of detection which the author has made so peculiarly his own. The suggestions for amendment of the Workmen's Compensation Act are all in the direction of increasing the powers of medical referees to decide issues of a purely medical nature, and will receive the assent of the medical profession. Under the law as it stands at present a case may only be referred to a medical referee on the application of both parties. The result naturally is that the side which has doubt about its position refuses to apply, and accordingly very few cases are so referred. The author's proposal that the matter shall be referred to a medical referee on the application to the court by either party is one which will be strongly endorsed by all who have had experience of these cases.

The author also calls attention to the fact that in many cases where medical points are at issue the judge still fails to summon a medical referee to sit with him as an assessor, although most of the cases turn upon medical evidence which is technical and may be conflicting. Sir John Collio's recommendation—that if either party desires to have a medical referee sitting as assessor, the judge should be compelled to grant the application—is entirely sound.

The interesting accounts given of some recent decisions, though more of legal than of medical importance, show that the author keeps himself in touch with events. The book is clearly written and should prove useful to those interested in the subject.

NOTES ON BOOKS.

It is little more than a year ago since we welcomed very warmly the appearance of the Report of the Departmental Committee appointed by the President of the Board of Education to inquire into the position of English in the educational system of England.⁹ No one can feel more strongly than we do the importance to the student of medicine of a good general education as a foundation for technical knowledge and for the exercise of a liberal profession. We believe, with the authors of that report, that a command of his own language should form an indispensable element in the training of the citizen, and we hold that this applies with peculiar force to the training of the medical practitioner. English, so much neglected in the past, is the essential basis of a liberal education for all Englishmen, and in a special degree for members of our profession. The present condition of English in schools is admittedly most unsatisfactory, and the reasons for this were stated at length in the Report; one defect—in schools where English is taught as a "subject"—is the undue stress laid upon formal grammar. Among recent school books which seem to show a movement in the right direction—that is, towards the inculcation of a living interest in the mother tongue, both as a means of precise communication and as a mode of artistic expression—we may mention *English Literature: The Rudiments of its Art and Craft*,¹⁰ by Mr. E. V. DOWNES, of which the second edition has lately come to us for notice. We have not space to discuss the plan and scope of this little work, and will only say that it appears to us to possess the great merit of being written by one who loves literature for its own sake and seeks to convey his enthusiasm to

the pupil. For this reason certain shortcomings will readily be overlooked by the fastidious student of English. No disparagement is meant when we express the opinion that an intelligent youth will get very much more good than harm from this agreeable introduction to the technique of English composition.

The *Annual Charities Register and Digest* published by the Charity Organization Society gives information, which cannot be found in the same form elsewhere, for those who occupy themselves in charitable work of any kind, more especially in London. The thirty-first edition, for 1922, which has just been issued¹¹ will be found as useful as its predecessors. It gives a classified list of all the institutions, societies, and bodies, in or available for the metropolis, which can be approached for relief in cases of affliction or distress, whether of body, mind, or estate. The detailed information is prefaced by a short summary of institutional finance during 1920, and here is pointed out the impossibility of drawing a sharp line between London charity and provincial charity. Particular care has again been taken to make the index both accurate and comprehensive.

The Charity Organization Society has issued simultaneously a smaller work entitled *The Prevention and Relief of Distress*,¹² being a handbook of information respecting the statutory and voluntary means available for the relief of distress and the improvement of social conditions. This embodies most of the material formerly contained in Sir Charles Loch's introduction to the *Charities Register and Digest*, entitled, "How to help cases of distress," and it is intended to be used as a reference book in conjunction with the *Register*. The aim is to supply the social worker or student with a working knowledge of the organizations, whether State, municipal, or voluntary, which deal with the relief of distress; to co-ordinate the information which should be familiar to persons administering relief; and to set forth principles and methods which experience has proved to be sound. Like the companion volume it is written principally from the point of view of the London worker, but a good deal of the material has a far wider application.

MEDICAL AND SURGICAL APPLIANCES.

Vein Needle Outfit for Collecting Blood from a Vein.
DR. A. CAMBELL (Medical Officer in Charge V.D. Treatment Centre, The Royal Portsmouth Hospital, Portsmouth) writes: Although the ordinary method of collecting blood from a vein by puncturing it with a needle and allowing the blood to flow into a test tube is quite a simple operation, it is sometimes difficult for the inexperienced to do it quickly and cleanly. Without a good deal of practice it is not easy to hold the needle and the test tube with the fingers of the same hand. I have devised a simple outfit which provides a rigid connexion between the needle and the test tube and at the same time ensures the blood being collected in a sterile manner. Soldered parallel to the needle is a tube of similar diameter but shorter in length. Attached to the two is a flat metal plate forming a winged grip. The twin needle is passed through a perforation set eccentrically in a rubber bung, which

sits tightly in a test tube of appropriate size. The object of the additional tube is to allow an exit for air to pass out as the blood flows into the tube. Holding the test tube, the point of the needle is plunged into the vein and the blood allowed to flow until the requisite quantity is obtained. After withdrawal of the needle it is removed from the bung by twisting and pulling on the grip gently, the bung then being pushed firmly home. The pressure of the neck of the test tube closes the perforation and prevents leakage. The length of the test tube is convenient for centrifuging and the outfit is enclosed in a wooden box and can be sent safely through the post. The outfit has been made for me by Messrs. Down Bros.

Soloid Urine Analysis Reagents.
Messrs. BURROUGHS, WELLCOME AND CO. have placed on the market a very handy set of six "soloid" urine analytical reagents. These reagents consist of citric agar, picric acid, potassium. A circular included in the of the "soloid" reagents. It is the only criticism to be offered is that the soloids do not dissolve very rapidly unless previously crushed into powder. In every other respect the collection of reagents satisfies all the claims put forward by the manufacturers.

¹⁰ *English Literature: The Rudiments of its Art and Craft.* By E. V. DOWNES, M.A. Senior English Master, High School for Boys, Newport, Mon. Second and revised edition. London: Hodder and Stoughton. 1922. (Cr. 8vo, pp. viii + 285. 4s. 6d. net.)

MOTOR NOTES FOR MEDICAL MEN.

BY H. MASSAC BUIST.

THE MOTOR CAR SHOW IN LONDON.

WHEREAS the majority of the passenger cars shown at the recent exhibition in Paris were the identical vehicles that appeared in the same building twelve months ago, in the case of the sixteenth International Passenger-Car Show that opened on Friday, November 3rd, under the patronage of the King, at Olympia, Kensington, and the White City, Shophord's Bush, London, there is practically not one vehicle, or chassis, staged which appeared last year. Though split into two buildings, as in Paris, the display in London differs from the French inasmuch as the latter contained pedal bicycles, motor bicycles, commercial motors, and marine motors, as well as motor cars and all manner of accessories, whereas the British one is confined solely to passenger cars and accessories for them. The exhibition in London, which will be open until Saturday, November 11th, is, too, of a more international character than the French exhibition, and much more so than any of the American shows, or than the German and other displays on the continent of Europe. All cars of note introduced to the public in Paris are shown in London, and the American industry is represented by nearly all its notable products; none of the few abstainers have new models of note embodying fresh ideas in regard to construction. By way of indicating at once the sheer variety of fresh material for consideration, I may mention that quite new models are introduced by the following firms among others: Argyll, Ariel, Aster, Austin, Angus-Sandersou, B.S.A., Bianchi, Biguan, Calthorpe, Case, Clyno, Coventry Premier, Crossley, Crouch, Delage, Delaunay-Belleville, Daimler, de Dion Bouton, Enfield-Allday, Ensign, Crown Ensign, Excelsior, Fiat, G.N., G.W.K., Gwynne, Humber, Hurtu, Lauch, N.P. (Salmons and Sons), Palladium, Paige-Jewett, Phoenix, Renault, Rover, Ruston-Hornsby, Singer, Straker-Squire, Sunbeam, Swift, Seabrook, Star, Talbot, Trojan, Turner, Unic, Vauxhall, Wolseley.

A NEW CHAPTER IN CHEAPER MOTORING.

Novelties, however, are not to be found solely in regard to new models. No less important a feature of this display is the evidence it affords of a complete change of conditions in regard to prices. A number of models of up-to-date design have been notably reduced in price despite the fact that they are being made better now because another year's experience of the cars in the hands of the public has been gained, and because in many cases they have been improved in regard to the details of design and equipment; such changes, though not sufficiently radical to constitute them wholly new models, are, nevertheless, sufficient to justify their being described as essentially 1923 products. The best way to indicate the scale of reductions is to select some prices for this year's improved products in respect of cars coming within the power and purse ranges likely to concern the average medical man. The facts are set out in tabular form in the next column.

The visitor to the British show who wishes to make himself acquainted with all the material offered within the range likely to be of interest to him will not be able to visit either Olympia or the White City separately and consider that he has seen all that will interest him as would have been possible had he gone to the French show, where the division of the exhibits was strictly logical in that no machine having an engine of 1,100 c.c.m. or less was eligible for display in the Grand Palais, and all the small-engined cars were displayed in ancillary buildings. The classification in London is solely by the luck of the ballot, so that the prospective buyer interested in any one size of car will have to go to both buildings in London. The arrangement is extremely inconvenient, but the Society of Motor Manufacturers and Traders had contracted for Olympia, which is in process of enlargement, and it was anticipated by some, though never by myself, that the work would be sufficiently far forward to enable all the vehicles for display to be housed within that building. A couple of months ago, however, it was plain that this was impossible, and it was decided to split the exhibition between the two buildings. The visitor, however, may be assured that next year it will be possible to get all the vehicles in the one building. Meantime, what with the reduction in petrol prices and in tyre and car costs, with consequent saving in the total sums of money for which vehicles have to be insured,

Tax.	Make.	Chassis Price.		Car Price.

8	Talbot	—	—	2	350	295

and the improvements incorporated in the various machines, it is plain that there is ample material for inspection on the comparative basis, which is the quickest way of becoming acquainted with what may be styled relative degrees of merit.

NEW MODELS ARE SMALLER TYPES.

As far as I have been able to discover—one cannot make sure until the doors of the exhibition shall have closed, so vast is the quantity of material for review—there is but one exception, the B.S.A., to the rule that every entirely new model introduced this year is smaller in regard to engine size, and cheaper in regard to price, than any previously on the given car builder's list. This is a noticeable tendency, as may be judged from the fact that when the first post-war exhibition was held the first thing to strike the visitor was that makers seemed to have vied with one another in the production of large models, the endeavour being apparently to see who could introduce the most costly chassis. Another point of direct interest to the medical man is that, when one speaks of the list price of a two- or of a four-seater car nowadays it is understood that that sum includes what is styled all-weather equipment—that is, hood scheme embracing side curtains and opaque panels opening and closing with the doors. Humber gives a further lead by standardizing all models with double wind screens and double-acting nickel and rubber wipers. These are of such appreciable service to the medical man that it is important to know that they can be obtained now for a fixed sum, which in practically all cases is less than the cost of the given models without such equipment twelve months ago. The chief causes for the fall in costs are the changed attitude of labour and reduced transport and raw material charges, though there are other factors, such as better manufacturing methods, better distribution and organization, and so forth. There is, however, one rather disconcerting trend against manufacturing progress as demonstrated by America in the policy of "one firm, one model." We had worked in Britain a long way towards that by the time war broke out, and there were indications that our experience of manufacturing during the war had led us to discover the value of that policy as applied to motoring; but events have not fulfilled this hope, and we find a large number of firms

this year introducing multi-model programmes of even more embarrassing variety than any known before the war; and a large number of firms are increasing their already large range of models. For example, for 1923 Austin increases his models from two to three, as he did last year from one to two. Again, Wolseley adds yet another to a programme that now embraces no less than six main chassis types. Of course, all this is because our export markets have been closed and we have had to try to sell more vehicles at home.

THE THREE NEW ENGINE SIZES.

In regard to taxation costs it is at least assured that there will be no change in the basis of arriving at horse-power for the purpose of Treasury rating. The Society of Motor Manufacturers and Traders decided months ago that no matter what happens in regard to the proposed reduction of the proportion of revenue to be raised from horse-power taxation if one of the schemes recommended—namely, that of a petrol tax—should go through, thereby bringing us back to a dual tax, nevertheless the basis of the Treasury rating of engines shall remain what it is to-day. Therefore the question whether to buy, say, a large-engined, cheap American car, or a small-engined, moderate-priced European car, is unaffected because the proportion of the tax payable in respect of the engine rating will remain exactly the same in ratio. Hence incidentally there is no likelihood of a taxation scheme affecting materially the trend of car development as represented by engine design. Whereas at the French show it was discovered that a number of what may be called the small fry in the industry—many not known here fortunately—are staking their all on what we would call the cycle car, there is very little evidence of that in the London show. British manufacturers seem to be intent on the evolution of the small car proper. While for competition purposes our organizations have persisted overlong in dividing small cars into those having engines not exceeding 1,500 c.c.m. (91½ cubic inches) and those having engines not exceeding 1,100 c.c.m. (67½ cubic inches), manufacturers standardizing cars of the smaller classes choose to take 1,000 c.c.m. (61 cubic inches) as the natural limit for a new class—the 1-litre class, and the 1½-litre class, supplementing the 2-litre or 122 cubic inches class that is also very popular, alike on the Continent and in this country. A number of Continental manufacturers are producing engines of the 2-litre class, and of the 4-cylinder type in particular, which come out in the main at between 10-h.p. and 12-h.p. rating, though some others would involve the payment of a yearly tax of £14 and even £16 under the present scheme.

OVERLOADING.

In regard to the 1,500 c.c.m. engined class, it was noted last year that there was a tendency to overload these types, chiefly because, where the engine was really efficient, the chassis were sometimes not made strong and large enough to take the ambitious bodies supplied. In this class to-day, however, there is not so much evidence of overloading. A very interesting further development this year is that not only are there more 6-cylinder engines in the 2,000 c.c.m. (122 cubic inches) class, but there are also some very notable 1,500 c.c.m. (91½ cubic inches) 6-cylinder engines, as witness, particularly, the 6-cylinder overhead-valve engined Talbot (£12 tax). Another small 6-cylinder in this class is the 12-h.p. Daimler of the double-sleeve valve type. There is also the 6-cylinder side-valve A.C. model. Though these are smaller 6-cylinder engines than we have had hitherto, they do not represent the extreme to which manufacturers have gone. For example, from Alsace there come two versions of the Mathis—one a 6-cylinder overhead-valve engine of 1,188 c.c.m. volume, and the other a 6-cylinder side-valve engine type of 1,140 c.c.m. volume. But these are rather exceptional propositions than otherwise. On the other hand, that the very small engine is regarded as a commercial proposition by British manufacturers is suggested by the introduction by Sir Herbert Austin of an £3 tax, 693 c.c.m., side-valve, 4-cylinder, water-cooled engined small car with single-plate clutch, gearbox embodying three speeds forward, spiral bevel-driven back axle, transverse front spring, quarter elliptic rear springs, dynamo lighting, mechanical starter operated from the seat, and all-weather body to seat two adults, a child, and luggage, and interchangeable brakes to all four wheels; the whole scales some 6½ cwt., and is listed at £225. This is an attempt at a new type of utility car. Rover, again, introduces a developed version of the well-established £8 tax, air-cooled, 2-cylinder chassis equipped with a four-seater body

to hold two adults and two children, or adjustable to accommodate two adults and an ample proportion of luggage—the whole listed with all-weather equipment complete for £190. In yet another direction we find the Armstrong-Siddeley organization producing, through a subsidiary concern, the Stoneleigh utility three-seater air-cooled car; that did so well in the Royal Scottish Automobile Club's trial; this £9 tax machine is listed this year, complete with clover-leaf three-seater body, adjustable for carrying luggage, for £185, as compared with £225 last year.

NEW BRITISH CAR BUILDERS.

There is also evidence in the Show of a quite unexpected tendency—an increase in the ranks of chassis producers at a time when, one would imagine, most folk would be extremely chary of embarking on such an enterprise. Yet some of it is in the nature of an almost... Instance the enterprise of the Astro... which for twenty-two years has produced... 12es that have been used in a vast number of cars of different names; this year it introduces a complete vehicle—a 6-cylinder £18 tax 2,618 c.c.m. tubular pushrod and rocker operated overhead-valve engined chassis wherein the valve seats are water cooled and aluminium pistons are used; the cylinder head design is a result of the firm's investigations into the problem of turbulence. This power plant has 1.23 mean effective pressure at 3,000 crankshaft turns a minute, and can be run from 170 to 3,200 r.p.m. The £535 chassis has a four-speed gearbox controlled by interlocking selector plus; weighs 1½ cwt., and the brake horse-power of the engine is 55 at 3,000 crankshaft turns a minute. Gwynne's, who manufacture the Albert car, now introduce an £8 tax 950 c.c.m. pushrod and rocker operated overhead-valve engined Gwynne car, the 4-cylinder power plant of which is distinctive by reason of the use of aluminium pistons and wick feed lubrication to the valve rockers. This chassis has a three-speed, constant mesh gearbox, mounted on the torque tube, the car being marketed, complete with clover-leaf coachwork, for 198 guineas. Again, the old-established coachbuilders, Salmons and Sons, of Newport Pagnoll, now bring forward a chassis styled the N.P. (presumably standing for Newport Pagnoll), the coachwork being notably superior to the average standardized. This is a £12 tax 1,795 c.c.m. machine with pushrod and tappet operated overhead-valve 4-cylinder engine; full cantilever rear springs and special means of taking up wear in the back axle bearings; the car complete with four-seater body being listed at £525, and as a two-seater at £495.

CHIEFLY CONCERNING NEW MODELS.

Regarding the Show in its international aspect, some of the outstanding features in quite new models of cars introduced by established makers may be touched on briefly. Thus the 1,693 c.c.m., 4-cylinder, overhead-valve engined Bignan is distinctive in having Hallett-Servo brakes operating on the front wheels, and no brakes acting directly on the rear wheels. Preceding in alphabetical order, Crossley introduces a 2,388 c.c.m., 4-cylinder, water-cooled, side-valve engined chassis with three-speed gearbox, selling at the price of £475, complete with body and equipment. The 12-h.p. Dolaro is a small car with a complete four-wheel braking system; as is the 2,614 c.c.m. Delaunay-Belleville with nickel-steel overhead-valve engine. In the latter case the Perret diagonally controlled front wheel brakes act in synchronism with the transmission brake, the hand-controlled brake acting independently directly on the rear wheels. Crouch introduces a 1,248 c.c.m. 4-cylinder car to sell at £235 as a two seater, the chassis being equipped with a 4-cylinder Anzani engine with aluminium pistons. From Belgium comes the 6-cylinder, 5,343 c.c.m., overhead-valve engined Excelsior car, of the type supplied to King Albert, and having Adex diagonally controlled, cable-operated brakes to all four wheels. The increasing use of aluminium pistons is illustrated in the 3,308 c.c.m. pushrod operated overhead-valve 4-cylinder engined de Dion Bouton, which has four wheel brakes and cantilever rear springs. Pushrod and rocker operated overhead valves are also used in the 2,485 c.c.m. 4-cylinder de Dion Bouton chassis which is available with or without brakes to all four wheels, at option.

For £275 Humber introduces a 985 c.c.m., water-cooled, overhead inlet valve, side-by-side exhaust valve, 4-cylinder two-seater, with detachable seat for carrying two children or ample luggage, and with all-weather equipment. The 990 c.c.m. 4-cylinder Angus-Sanderson (£275) is a two-seater type with dickcy. Both the large Humber chassis; previously standardized, are brought forward this year with engines having the new style of valve system. All three models are standardized, with double wind screen and double-action nickel and rubber wiper. A new Singer model with a 4-cylinder, pushrod operated, overhead valve, 1,036 c.c.m. water-cooled engine, and the Coventry Premier, with the

same size and type of engine, are introduced, the former having magneto and the latter dynamo and battery ignition. The Straker-Squire car shown comes within the 1½-litre class, being a 1,460 c.c.m., pushrod and rocker lever operated overhead valve 6-cylinder engine chassis, with gearbox having four speeds forward and with semi-elliptic springs fore and aft, the whole selling as a two-seater complete for £425. A sports version of the nominal 14-h.p. Sunbeam car with overhead valve 4-cylinder engine, of 1,954 c.c.m. volume, is introduced this year to give greater power; a special carburettor, inlet piping, and pistons are furnished, the vehicle achieving a maximum speed of over 65 miles an hour on the flat, and the chassis being marketed at £585. Swift has produced a quarter elliptic sprung four-seater, with a 4-cylinder, side-valve engine of 1,037 c.c.m. volume.

MISCELLANEOUS NEW SCHEMES.

In the 1½-litre class, the aforementioned 6-cylinder overhead-valve engine 1,454 c.c.m. Talbot chassis is listed at £465, and with 4½-seater body and all-weather equipment at £575. In addition to fitting the large 28-90-h.p. Vauxhall with an overhead-valve engine, a nominal 23-60-h.p. entirely new chassis is introduced this year; it has 3,969 c.c.m. pushrod operated overhead 4-cylinder valve engine, the chassis scaling 23 cwt., having four speeds forward, and being listed at £1,150 complete. Ruston-Hornsey introduces a 2,614 c.c.m. 4-cylinder and a 3,308 c.c.m. 4-cylinder side-valve engine chassis of conventional design, to sell at £525 and at £575 respectively, with 4½-seater body in each case. The new 1,463 c.c.m. Seabrook sports model has an overhead-valve Meadows engine. The Star Company of Wolverhampton introduces a 2,169 c.c.m. nominal 18 h.p. car with two

covering three cylinders only; a crankshaft equipped with integral balance weights; a single dry-plate clutch; and a gearbox providing four speeds forward. Wolseley supplements its list of models by bringing forward a side-valve engine, nominal 14-h.p., 4-cylinder family car of 2,613 c.c.m. engine volume, listed complete with 4½-seater coachwork, for £525 only. Argyll introduces a 1,496 c.c.m. 4-cylinder single-sleeve valve engine chassis, with four-speed gearbox, controlled centrally, to sell as a four-seater touring car at £495.

Among the small disc adhesion driven types of cars, G.W.K. has an interesting development this year in bringing forward a type wherein the driving disc is fashioned of aluminium and has triple section cork insertions, divided by thin aluminium rings, round the periphery; thus it is hoped to prevent warping, or bursting, of the discs, and to deal also with the heat problems involved. From France comes the 12-h.p. 4-cylinder Unic with newly designed front axle, rear cantilever springs each set above a quarter elliptic spring; mechanical tyre pump incorporated with the gearbox; and pedal-operated dustproof front wheel brakes functioning in conjunction with the brake on the propeller shaft, the wearing surfaces being supplied automatically with lubricant each time the brakes are applied.

FRONT WHEEL BRAKE DEVELOPMENTS.

Sunbeam introduces a developed form of the £24 tax, 4,824 c.c.m., pushrod operated overhead valve, monobloc, 6-cylinder engine chassis with pedal operated Servo motor bolted on to the gearbox. By this means large diameter brakes are applied to all four wheels on the Perrot diagonal system, the front drums being ribbed like the rear ones for cooling. The front axle is designed specially to take the torque, or twisting strain, of brake application. The one piece stamping has an I-section between the two springs, but takes a circular form from, and including, the spring pads outwards to the stub axle; this design is the result of experience in racing; it is the first standardized car to deal with the exceedingly important problem of braking strains. In like fashion Fiat introduces a 26.9-h.p. 6-cylinder overhead-valve engine model wherein the gearbox is used for the hydraulic application of the brakes on the principle of Servo mechanism, which may be described, broadly, as centrifugal force. But the Fiat design is distinctive because, should the gearbox be starved of oil through neglect or any other cause, it would nevertheless be possible to supply the front wheel brakes merely by using the lever in the ordinary way, when the action would be direct by lever and rod. This firm also discovered, quite independently, through racing, the importance of dealing with the twisting strain on the axle; this year's 2-litre Sunbeam and Fiat Grand Prix racers are both distinctive in having tubular axles for lightness sake, whereas in the standard products the axles are built solid. This very important mechanical development will presently affect all motor users, because as the car is lightened and the efficiency of power plant increased the possible means of braking must be increased, because the lighter the vehicle the less the road adhesion per wheel, therefore the less the

brake application possible. Anyone now considering the purchase of a car equipped with front wheel brakes should require a demonstration of the ability of the vehicle to negotiate a turn during application of the front wheel brakes. I write this because there is introduced at least one car with brakes to all four wheels in connexion with which the designer intends that they shall be used only when the car is running straight, and not at a corner or turn. This must be due to the method of control whereby to apply such brakes when making a turn would be to interfere with the steering and so cause skidding. But inasmuch as all car design should be governed by a knowledge of what is instinctive in nature it will be appreciated that any such braking system is impracticable, and can lead only to dangerous situations since, if a driver is provided with a lever the pulling of which he knows applies braking effort, and he finds he has approached a corner too fast and is dashing to disaster, it is certain that he will not let go that lever at the critical moment, but will instead pull it to the utmost, with dangerous consequence to himself, passengers, and other users of the highway.

SMALL SIX-CYLINDER SLEEVE VALVE ENGINES.

The two outstanding mechanical features of all new car design concern brakes and engine valves. Unquestionably the overhead valve is being increasingly used, though some manufacturers, including notably such new members of the American industry as use overhead valves, do so on principles that do not obtain that higher proportion of efficiency, as represented either by power or economy of fuel, which should be the sole reason for employing this gear; if properly done great saving of heat loss can be effected. But the overhead-valve engine has not by any means ousted the poppet side set type. Nor has it eliminated the sleeve type. In fact the last named has been developed notably this year, as witness the showing in the French long distance road race for the Grand Prix de Tourisme, wherein the cars were run on a fuel allowance, and loaded with the equivalent of four passengers, the running weight of each scaling approximately two tons, yet 65 miles an hour mean speed was achieved by the winner. All the cars in this race were equipped with double-sleeve valve engines having a mean effective pressure of 6.3 to 1, which is unprecedentedly high for standard car practice. These engines turned at a speed we should have thought quite impracticable for this type in the pre-war period. Minerva introduces some interesting smaller double-sleeve valve engine types, and all the novelties from the firm that pioneered the whole proposition, the Daimler Company, are in the direction of making this type more popular. Thus, the Daimler 21-h.p., 30-h.p., and 45-h.p. 6-cylinder models are now supplemented by a 12-h.p. 59 by 94 mm. (= 1,541), 70 c.c.m., 6-cylinder double-sleeve valve engine chassis, as well as by a 16-h.p., 65.5 by 104 mm. (= 2,166), 74 c.c.m. double-sleeve valve 6-cylinder engine chassis, to be sold at £550 and £625 respectively; it is sold also with four-seater bodies. Further, through its associated concern, the Birmingham Small Arms Company, this firm introduces a 4-cylinder double-sleeve valve, nominal 11-h.p. B.S.A. car, the bore measurement being 65.5 mm. and the piston travel 104 mm., and the chassis details being almost the same as those of the air-cooled B.S.A. model introduced as a two-seater last year.

There is also a 6-cylinder B.S.A. model of the same engine size as the 12-h.p. Daimler, but the chassis type is, of course, utterly different. Thus the Daimler B.S.A. programme of fifty-seven models now includes vehicles costing complete from £230 to £2,000, a matter of interest to members of the medical profession being the introduction of complete 6-cylinder small saloon and coupé Daimler types at popular prices, the smaller Daimler models being akin to the largest ones alike in quality and finish; also, in regard to the design, the only apparent constructional difference is the use of semi-elliptic rear springs. In regard to the B.S.A. cars standardized complete with coachwork, one of the cheapest is an interesting variant of the all-weather side paneling scheme. In this the panels slide longitudinally when it is desired to have access either to the front or to the back seats, or to provide ventilation to the vehicle by that means. The other still more novel item is on the all weather type of body wherein, nevertheless, there are windows that rise and fall as though they were glass. They are, however, made of particularly hard celluloid, to the gain of clearness. Of course, by this means the weight of the window is practically negligible. Further, it is possible for the window as a whole to bend when it is raised or lowered, as it is necessary to accommodate the curved lines of the coachwork. Voisin, hitherto associated with the largest and most expensive types of car, also introduces an 8-10-h.p. double-sleeve valve engine small car with front wheel brakes. The 6-8-h.p. (travel rating 5-h.p.) Renault has a mixture controller

gear mounted on the steering column. The 4-cylinder water-cooled engine has 58 by 90 mm. bore and stroke; the gearbox three speeds forward; dynamotor electric light equipment is standard, and a transverse rear spring is used.

THE BATTLE OF THE VALVES.

Even Rolls-Royce is among those making smaller cars. This firm introduces a nominal 20-h.p. 6-cylinder machine with three-speed gearbox controlled centrally, and semi-elliptic springs fore and aft. But this type is not shown at Olympia, the firm regarding it as entirely supplementary to the large 6-cylinder side-valve engine type, which is represented at the exhibition by numerous examples. Nevertheless, the smaller machine is interesting as being the first-fruits of the firm's unique experience in aircraft engine construction during the war and bringing the make within the price range of "Harley Street." Thus, as we have in the latest motor spirits marketed those that are mixtures of benzol with petrol and which are known as "fifty-fifty," so we have a number of the leading manufacturers in the motor world, including Rolls-Royce, Fiat, Vauxhall, and Wolseley, exploiting what may be called a "fifty-fifty" valve policy. For instance, Fiat has a big overhead-valve 6-cylinder engine car this year, but the 4-cylinder types and the 20-30 h.p. 6-cylinder model have side valves. Vauxhall uses side valves for the nominal 14-h.p. type, and overhead-valve engines for the two larger chassis; and Wolseley uses side valves for its 6-cylinder, for its 14-h.p. 4-cylinder, and for its 2-cylinder 7 h.p. chassis; but overhead valves for its 10-h.p. and for its 15-h.p. 4-cylinder chassis. Again, among small car builders G.N. offers a chassis with an engine having side valves only, as distinct from overhead inlet and side exhaust valves, and another chassis having a 4-cylinder engine with overhead inlet and exhaust valves. In other words, as we have noted, has designed an engine with overhead inlet valves and side-by-side exhaust valves. Notable novelties introduced from the Continent chiefly range in the 2,000 c.c.m. (122 cubic inches) engine volume, and in the 1,500 c.c.m. (91½ cubic inches) cylinder content classes, as witness the Ansaldo 2,000 c.c.m. 6-cylinder model; the Ballot 2,000 c.c.m. touring model; and the Bugatti 2,000 c.c.m. 8-cylinder model of entirely new design with, incidentally, sparking plugs approximately the size of cigarettes only. Nominal 10-h.p. types are introduced from the Continent by Hurta, Léon Bollée, Lorraine-Dietrich, Salomon, Th. Schmiedler, and Vermon. Perhaps the most interesting of all tendencies, however, to medical men is the before-mentioned re-entry of no less renowned a firm than Renault into the quite small car market.

A RADICAL DEPARTURE IN CAR DESIGN.

Unquestionably no departure so radical, without freakishness, is produced as by Lancia on behalf of Italy in a 13.9-h.p., 4-cylinder, overhead-valve engine car with a frameless chassis. This notable development is achieved by the use of a steel pressing for the frame of the coachwork, which is all pressed in one piece, including the frame, for the radiator as well as the tube for enveloping the propeller shaft. The structure is therefore considered to be sufficiently strong to act as chassis frame as well as coachwork frame. It is a wonderful design, entirely practicable and resulting in a remarkably light vehicle, the channel section of stamping being used. Other notable features in this chassis are the overhead-valve engine on the principle that was introduced some time ago in a 12-cylinder model, and which is notable for the extraordinary brevity of the over-all length. In the case of the present 4-cylinder type the same system is used whereby the cylinders are staggered in a 20 degree V only, resulting in a crankshaft of extraordinary rigidity and shortness, the whole power plant giving the first impression that it must be a 2-cylinder type.

GENERAL TENDENCIES.

No one springing system is predominant; nor is any one ignition system, though it would appear that the coil ignition principle is gradually gaining ground. There are, however, notable developments in connexion with magneto, particularly the new style B.L.I.C. introduced by Vickers, and concerning which Dr. Turner read a notable paper at the recent meeting of the British Association. This is an extraordinarily light, durable, and simple system of magneto. It is remarkable for the efficiency of the spark at engine speeds lower than those at which it is possible to achieve satisfactory carburation, and, at the other extreme, for efficient sparking at the high revolutions at which the most efficient modern engines work. Some manufacturers introduce steering wheels that are still larger in diameter, but of a smaller section, the claim being that steering is rendered easier. Of course, if steering gear is designed properly, there should be no call for this change, since

we have been in the habit of using wheels almost excessively large for the convenience of the driver and of those seated next him. Properly designed cars should not require the driver to sit with a knee in a knee. Nor should it be necessary for him to make exaggerated movements, as has to be done too often with the steering wheel to make a car deviate even slightly out of the straight path—as, for example, when encountering other vehicles on the road. Than that, no spectacle is more ordinary. It is merely a demonstration of badly designed steering. Further, the use of a smaller section wheel is not desirable on the grounds of comfort, as any one can appreciate who has to do half a day's or a day's driving at a spoil. The size in general use hitherto has been the minimum of creep from overcontraction of the fingers is to be avoided. Properly designed steering is so light nowadays as not to need the use of a wheel of large diameter. We want wider wind screens, not steering wheels.

A solution of the problem of using lower grade fuel with higher compression ratios, regarding the carbon formation process and eliminating "pinking," is furnished by the introduction of the Hobson "non-pinker" (licensed Ricardo and Dodson Bi-fuel Patents), an apparatus supplementary to the carburettor, but the control of which is coupled up with the carburettor control, so that the "non-pinker" is brought into operation at such openings of the throttle as would produce "pinking" conditions without its use. For this purpose it is used solely with water, so obtaining in current type engines run on low-grade fuel the same effects as are at present obtained only by the use of benzol, or of benzol mixed with petrol. In regard to the future of engine design, this development renders it possible to raise compression ratios from 4.6:1 (the present average standardized) to 6:1, which means opening a new chapter of possibilities in power plant design and production. But in such higher compression engines, of course, the "non-pinker" would not be used to run on water; instead, it would be run on alcohol, hence you would really have the true bi-fuel form of carburettor.

EXAMPLES OF LINES OF DEVELOPMENT.

Auto-Carriers is one of the first firms to introduce a small 6-cylinder car. Its £16 tax side-valve engine 6-cylinder chassis with magneto or dynamo ignition at option, right hand gear and brake controls, worm drive and steel disc wheels, is listed, complete with electric engine starting and car lighting set, for £535, or, as a four-seater "Royal" model, at £700. The £12 tax 4-cylinder A.C., with 4 mm. bigger bore measurement, is listed, as a two-seater, at £475 complete with dickey. A notable price proposition among the new small machines is the £9 tax "Ariel Nino" with single shell family four-seater body and horizontally opposed, twin-cylinder, water-cooled engine, rated at £235, with all weather side curtains opening and closing with the door, and disc wheels. This is, therefore, one of the examples in which a notable effort is made to overcome the problem of the dickey seat for small cars, in that in the new Ariel when the hood is raised the occupants of every seat are protected from the elements. The 10 h.p. Enfield-Allday two-seater is marketed at £445 and the four-seater at £450; the firm, which has made great progress during the last year, has introduced a new 12-h.p. 4-cylinder model with an engine of 1,757.33 c.c.m. volume, three bearing crankshafts, and forced feed lubrication, together with a gearbox giving four speeds forward, the control being by the driver's right hand. The rear axle is spiral bevel driven, and the rear springing is a version of the cantilever principle. The 1923 £11 tax Galloway car is rated at 10-20-h.p. by the makers, the engine size being somewhat increased (66.5 mm. bore by 110 mm. piston travel). Spring box clamps are employed in connexion with the suspension system; the tools are housed in a drawer under the running board. The side curtains are accommodated in the rear of the driving seat when not in use; they are quickly detachable and have ample opaque areas, so that when the vehicle is used as a completely closed four-seater type there is good natural illumination for its occupants. The Galloway two-seater car, shown with open body and adjustable driver's seat and dickey, is painted light brown and suitably upholstered, being listed at £295 complete, and the four-seater, with three doors, at £350, in both instances delivered at the works.

NEW IDEAS IN BODY SCHEMES.

To meet a demand for a Calcott car of slightly heavier proportions an entirely new 13.9-h.p. 4-cylinder model with an engine volume of 2120.57 c.c.m. has been introduced with an enclosed oiling system giving the power plant a neat appearance. The gearbox has four speeds forward, and the gate change is accommodated on the driver's right so that there is no question of interfering with the convenience of the occupants in the front seat. Both foot and hand operated brakes act direct, side by side, on drums attached to the rear

wheels. The final drive is by spiral bevel gear. The particular shade of blue adopted by the firm as standard this year is of a distinctive and attractive hue. This 13.9-h.p. coupé is listed at £425. The 10.5-h.p. 4-cylinder Calcott model is marketed as a two-seater with double dickey, double wind-screen and side curtains, together with 12-volt electrical engine starting and car lighting set, for £325. A new design of convertible coachwork and certain chassis refinements are features of the Hillman programme for the coming season. Note should be made of the very clever manner in which the windows have been made particularly wide, including those furnished to the types with collapsible hoods; the easy adjustments for reach provided by simple and rapidly operating mechanism in connexion with the seats, the maximum range being no less than 13 inches; the carrying of the side windows when out of use in a special compartment provided behind the seat, and especially the ingenious method whereby the side screens can be so set when the top is furled that they serve as an excellent means of protecting the rear passengers, in the style of a V-shaped wind screen. By means of a distance piece the side screen can be set slightly open, a point which will be much appreciated in many circumstances of driving. Another novelty is the furnishing of a locker on the front side of the dash to serve for a tool kit. In regard to the engine, the three-bearing crankshaft is now balanced rotationally and statically, as are the flywheel, the clutch, and the clutch shaft. By reason of the improvements in detail the Hillman engine develops more power; the exhaust box has been increased in size, and larger gears with helical teeth are used in connexion with the timing details.

PROTECTING ALL PASSENGERS ADEQUATELY.

Apart from notable reductions in price, perhaps the outstanding feature of the Rover programme is the introduction of the single shell type four-seater body on one of the 8-h.p. models listed complete for £190, thereby setting an entirely new standard of cost, for the hood completely encloses the occupants of all seats when in service. There have been improvements, likewise, in regard to the 12-h.p. Rover car, the engine of which now has pressure-fed lubrication. The 12-h.p. two-seater has been reduced £100 in price to £525, and the 12-h.p. four-seater a similar amount to £555; the coupé body with fixed top is now listed £100 cheaper at £450, and with drop-head type top £125 cheaper at £375. Again, the 8-h.p. two-seater, including all-weather side curtain opening with the door, is reduced no less than £40 to £180. Moreover, last year's price did not include side curtains. The Standard Company has given notable attention to the question of ample interior light in its new models; two new 13.9-h.p. Standard saloon types are introduced: one has smart square coachwork lines, an exceptionally natural interior lighting scheme, together with unusually long leg room and complete fittings, including adjustable seats in front. In the Standard special saloon a transverse spare wheel carrier is furnished at the rear. The 8-h.p. model, which was introduced last year, is in a somewhat different form, and is shown both as a chassis and as a two-seater with dickey. But stand space does not permit the display of this type as a four-seater, which is to be regretted, for it accommodates four persons without excessive overhang at the rear. These small cars, like the larger Standard models, are fitted with all-weather side panels in connexion with a collapsible hood—a principle pioneered by the firm and now becoming universal. The 8-h.p. car has now an electrical engine starter in place of hand-operated equipment, and magneto ignition instead of the battery system first employed. The reductions in the whole range of this firm's car prices are great. The 4-cylinder Waverley types are rated respectively at 11 and 15 h.p., the standard 11-h.p. two-seater being listed at £325 and the model de luxe four-seater at £450; while the 15-h.p. model de luxe five-seater costs £595, and the four-seater coupé with three doors £750. The touring types are fitted with all-weather curtains. In the 9.5-h.p. 4-cylinder 1,087 c.cm. £10 tax Rhode we have a four-seater car listed complete at £250, or, with self-starter, £15 extra; or as a coupé at £325, with overhead valve gear, detachable cylinder head, Cox carburettor, Brolt electrical engine starter, and magneto ignition, together with thermo-siphon cooling, a gearbox giving three speeds forward, and spiral bevel final drive. The suspension is by quarter elliptic springs fore and aft. Detachable disc wheels are standard, the vehicle having a road clearance of 8 in., an over-all length of 11 ft., a shellbox of 8 ft. 6 in., and a track of 3 ft. 10½ in.

ACCESSORIES.

In regard to exhibits by coachmakers, one notes that Offord and Sons display three types of all-weather, all-purpose cars, each of moderate power, the 12.8-h.p. 4-cylinder Austin all-purpose carriage having a featherweight Offord

body to seat five; the scheme is designed specially to meet the requirements of medical practitioners. The wide seat for three persons in front gives ample leg room for a tall driver. The hood is of special design and is supplemented with side curtains that open and close with the doors. There is a spare wheel and side curtain lockers under the seat. There are doors on both sides for the convenience of the driver, the colour scheme being blue-grey pleated but in black and upholstered in dark blue-grey antique leather at £565 complete. The 15.9-h.p. 4-cylinder Humber is an all-weather car which also accommodates five persons and has special convenience of entry by reason of an ingenious scheme of staggered doors, and sliding armchairs to the front. Special elbow rests are provided for the rear seats when occupied by two persons only. The 18.2-h.p. 4-cylinder Buick has also a featherweight, all-weather Offord body; but the accommodation in this case is for four, the price being £595 complete.

Reference was made in these columns a fortnight ago to the extraordinary change that has come over tyre construction and costs. Therefore it will suffice here to note that the Dunlop exhibit affords convenient opportunity for examining the entirely different construction now standardized on the cord principle with headed edge all-rubber treads that is, perhaps, the of current tyre development as applied to standard motor cars. The prices, covers with tubes included, are less than the pre-war cost, though many of these pneumatics will give 18,000 miles service against an average of about 4,000 miles before the war. To obviate the aggravating defect, often manifest in the past, of the walls of an outer cover bursting before the tread shows signs of approaching the end of its useful life, the Beldam Tyre Company shows the special design of rubber treads to prevent this trouble; these have a number of side projections which act as buttresses, with the result that a thick tread can be provided to make contact with the road without the walls flexing along a definite line of the fabric and causing localized stress and wear. Apart from the well-known Duco spring gaiters, Brown Brothers exhibit a range of Duco dipping headlights, actuated by means of Bowden cable and lever control, the fittings being arranged to drop on the prongs of existing brackets. The display of the full range of the latest Zenith carburettor designs is supplemented by a special set of carburettors with adaptation, or inlet pipes, enabling them to be fitted easily to a number of popular motor cars. Among the comprehensive array of articles displayed by Gamage are the latest fashions in motor clothing for the winter months, including the slip-on, roomy, waterproof umbrella coat fitted with rubber neck. One of the useful exhibits on this stand is the simple foot-warmer, which shows certain practical improvements on its prototype marketed before the war.

In conclusion, while I have made every effort to be accurate in the foregoing account of novel features at the show, nevertheless it is necessary to put on record the fact that I have never known, in the course of the whole series, such difficulty in arriving at the facts. There have been choppings and changings of policy up to the last moment. Therefore I should be obliged if any manufacturers concerned would draw attention to any details in this account which do not correspond absolutely with their programmes as decided on finally for the forthcoming season, to the end that the facts concerning the finally approved schemes may be mentioned next week.

AN outbreak of 51 cases of poliomyelitis in children, with 5 deaths, and 2 fatal cases in adults, has occurred at Tübingen. The fatal cases all showed signs of Landry's paralysis. Twenty-seven cases of poliomyelitis have recently occurred at Marburg, and all the schools have been closed.

ACCORDING to the census of 1921 the population of France has fallen since 1911 from 39,604,892 to 37,499,917, while the number of foreigners has increased by 417,763, so that there are about 2½ million French inhabitants less than in 1911. Only eight of the ninety departments have shown an increase of population.

OFFICIAL statistics show that the mortality has been higher and the birth rate lower in the forty-six large towns of Germany during the first half of this year than in the corresponding period of 1921. The mortality from tuberculosis is somewhat higher, while that from infectious diseases in children is lower.

THE late Mr. John Graham, farmer, of Methven, Perthshire, who died in June last, leaving personal estate valued for probate at £131,724, has bequeathed, subject to numerous bequests, the residue of his estate, which is expected to amount to about £50,000, to the Perth County and City Royal Infirmary.

SATURDAY, NOVEMBER 4TH, 1922.

* Notes of the preliminary reports made by Professor Macleod, Dr. F. G. Banting, Mr. C. H. Best, and their collaborators, were published in our columns of July 22nd, 1922, p. 140, and September 9th, p. 480.

London*, 1922, 1923, 1924, 1925, 1926, 1927, 1928, 1929, 1930, 1931, 1932, 1933, 1934, 1935, 1936, 1937, 1938, 1939, 1940, 1941, 1942, 1943, 1944, 1945, 1946, 1947, 1948, 1949, 1950, 1951, 1952, 1953, 1954, 1955, 1956, 1957, 1958, 1959, 1960, 1961, 1962, 1963, 1964, 1965, 1966, 1967, 1968, 1969, 1970, 1971, 1972, 1973, 1974, 1975, 1976, 1977, 1978, 1979, 1980, 1981, 1982, 1983, 1984, 1985, 1986, 1987, 1988, 1989, 1990, 1991, 1992, 1993, 1994, 1995, 1996, 1997, 1998, 1999, 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023, 2024, 2025, 2026, 2027, 2028, 2029, 2030, 2031, 2032, 2033, 2034, 2035, 2036, 2037, 2038, 2039, 2040, 2041, 2042, 2043, 2044, 2045, 2046, 2047, 2048, 2049, 2050, 2051, 2052, 2053, 2054, 2055, 2056, 2057, 2058, 2059, 2060, 2061, 2062, 2063, 2064, 2065, 2066, 2067, 2068, 2069, 2070, 2071, 2072, 2073, 2074, 2075, 2076, 2077, 2078, 2079, 2080, 2081, 2082, 2083, 2084, 2085, 2086, 2087, 2088, 2089, 2090, 2091, 2092, 2093, 2094, 2095, 2096, 2097, 2098, 2099, 2100, 2101, 2102, 2103, 2104, 2105, 2106, 2107, 2108, 2109, 2110, 2111, 2112, 2113, 2114, 2115, 2116, 2117, 2118, 2119, 2120, 2121, 2122, 2123, 2124, 2125, 2126, 2127, 2128, 2129, 2130, 2131, 2132, 2133, 2134, 2135, 2136, 2137, 2138, 2139, 2140, 2141, 2142, 2143, 2144, 2145, 2146, 2147, 2148, 2149, 2150, 2151, 2152, 2153, 2154, 2155, 2156, 2157, 2158, 2159, 2160, 2161, 2162, 2163, 2164, 2165, 2166, 2167, 2168, 2169, 2170, 2171, 2172, 2173, 2174, 2175, 2176, 2177, 2178, 2179, 2180, 2181, 2182, 2183, 2184, 2185, 2186, 2187, 2188, 2189, 2190, 2191, 2192, 2193, 2194, 2195, 2196, 2197, 2198, 2199, 2200, 2201, 2202, 2203, 2204, 2205, 2206, 2207, 2208, 2209, 2210, 2211, 2212, 2213, 2214, 2215, 2216, 2217, 2218, 2219, 2220, 2221, 2222, 2223, 2224, 2225, 2226, 2227, 2228, 2229, 2230, 2231, 2232, 2233, 2234, 2235, 2236, 2237, 2238, 2239, 2240, 2241, 2242, 2243, 2244, 2245, 2246, 2247, 2248, 2249, 2250, 2251, 2252, 2253, 2254, 2255, 2256, 2257, 2258, 2259, 2260, 2261, 2262, 2263, 2264, 2265, 2266, 2267, 2268, 2269, 2270, 2271, 2272, 2273, 2274, 2275, 2276, 2277, 2278, 2279, 2280, 2281, 2282, 2283, 2284, 2285, 2286, 2287, 2288, 2289, 2290, 2291, 2292, 2293, 2294, 2295, 2296, 2297, 2298, 2299, 2300, 2301, 2302, 2303, 2304, 2305, 2306, 2307, 2308, 2309, 2310, 2311, 2312, 2313, 2314, 2315, 2316, 2317, 2318, 2319, 2320, 2321, 2322, 2323, 2324, 2325, 2326, 2327, 2328, 2329, 2330, 2331, 2332, 2333, 2334, 2335, 2336, 2337, 2338, 2339, 2340, 2341, 2342, 2343, 2344, 2345, 2346, 2347, 2348, 2349, 2350, 2351, 2352, 2353, 2354, 2355, 2356, 2357, 2358, 2359, 2360, 2361, 2362, 2363, 2364, 2365, 2366, 2367, 2368, 2369, 2370, 2371, 2372, 2373, 2374, 2375, 2376, 2377, 2378, 2379, 2380, 2381, 2382, 2383, 2384, 2385, 2386, 2387, 2388, 2389, 2390, 2391, 2392, 2393, 2394, 2395, 2396, 2397, 2398, 2399, 2400, 2401, 2402, 2403, 2404, 2405, 2406, 2407, 2408, 2409, 2410, 2411, 2412, 2413, 2414, 2415, 2416, 2417, 2418, 2419, 2420, 2421, 2422, 2423, 2424, 2425, 2426, 2427, 2428, 2429, 2430, 2431, 2432, 2433, 2434, 2435, 2436, 2437, 2438, 2439, 2440, 2441, 2442, 2443, 2444, 2445, 2446, 2447, 2448, 2449, 2450, 2451, 2452, 2453, 2454, 2455, 2456, 2457, 2458, 2459, 2460, 2461, 2462, 2463, 2464, 2465, 2466, 2467, 2468, 2469, 2470, 2471, 2472, 2473, 2474, 2475, 2476, 2477, 2478, 2479, 2480, 2481, 2482, 2483, 2484, 2485, 2486, 2487, 2488, 2489, 2490, 2491, 2492, 2493, 2494, 2495, 2496, 2497, 2498, 2499, 2500, 2501, 2502, 2503, 2504, 2505, 2506, 2507, 2508, 2509, 2510, 2511, 2512, 2513, 2514, 2515, 2516, 2517, 2518, 2519, 2520, 2521, 2522, 2523, 2524, 2525, 2526, 2527, 2528, 2529, 2530, 2531, 2532, 2533, 2534, 2535, 2536, 2537, 2538, 2539, 2540, 2541, 2542, 2543, 2544, 2545, 2546, 2547, 2548, 2549, 2550, 2551, 2552, 2553, 2554, 2555, 2556, 2557, 2558, 2559, 2560, 2561, 2562, 2563, 2564, 2565, 2566, 2567, 2568, 2569, 2570, 2571, 2572, 2573, 2574, 2575, 2576,

history of his cult which is quite consistent with this. His history and that of his cult is indeed surprisingly like that of the Egyptian physician-god Imhotep, whom we know to have been an historic personage. Dr. Farnell is very convincing on this parallel, and he is evidently disposed to regard Aesculapius as of human origin, though he expresses himself with caution. On this view we may suppose that the original Aesculapius was a real practitioner of medicine who exercised his art in Thessaly somewhere about the year 1000 B.C. It is in considering the relation of the later Aesculapian worship to the development of medical science that much more debatable issues are raised.

The cult of the physician Aesculapius as a god which thus arose in the first instance at Trikkia appears to have been associated with the serpent from a very early date. The great historic centre of the cult, Epidaurus in the Argolic peninsula, was secondary to that in Thessaly. It was, however, chiefly from Epidaurus that the worship of Aesculapius seems to have spread throughout the ancient world, and among the most interesting of its later centres were those of Cos, Athens, Pergamon, Alexandria, and Rome. At Epidaurus the extensive ruins were long ago excavated by the now venerable Professor Cavvadias, whose son, at the recent Congress of the History of Medicine in London, gave a review of the relation, or rather the want of relation, of the medical profession to the Aesculapian worship in antiquity. At Cos similar excavations by the Germans described by Dr. Herzog have been less productive. Concerning the migration of the god to Rome, Livy and Ovid give circumstantial accounts of how the sibylline books during the plague of 293 B.C. induced the State to send an embassy to Epidaurus to seek help from Aesculapius. The ship returned, under the god's favour, bearing the sacred serpents, and stopped at an island in the Tiber where the animals chose to land. A temple arose there, and the sanatorium in connexion with it became famous in imperial times. Traces of the temple can still be seen on the island of St. Bartolommeo, part of the rock of which is carved into the form of a ship's poop decorated with a serpent twined around a staff.

The problem concerning the Aesculapian cult that must especially interest our profession is whether and how far, if at all, the worship of the god was associated with the development of scientific medicine. The worship of Aesculapius reached in later times a high degree of spirituality. Locally, and under special conditions, he even ultimately attained the rank of a supreme and perhaps universal god whose cult bore certain obvious parallels to that of Christianity. Speaking generally, however, his worship was on a low plane of folk belief and associated with a great amount of priestly deception, some of which was certainly wilful. We know from several writers that the practices of the Aesculapian priesthood were a subject of derision among the better educated and more level-headed of the ancients. So far as we are able to see, there is no trace either in its higher or lower development of any of the elements out of which science could be built. Furthermore, though many medical men, including Hippocrates himself, are spoken of by ancient writers as "Asclepiads," there is no evidence in the whole of the literature of medical antiquity of the association of a medical man of scientific repute with the worship of the god. Moreover, we do not know what the term "Asclepiad" really implies, for, though we assume it to involve membership of a physicians' guild, we can but guess at the nature and claims of membership of a company of which we know absolutely nothing. It seems more than probable, however, that an Asclepiad was not in any sense a *priest* of Aesculapius. It is true that instances can be adduced of professional physicians, otherwise almost unknown, who were actually priests of Aesculapius, and that some

medical men were accustomed to sacrifice to the god. But this is no ground for asserting that medicine grew out of Aesculapian worship.

That there is a field in which science and religion may be and are of use one to the other all medical men will most readily admit. It is yet a patent fact of history—a fact which Dr. Farnell himself sufficiently emphasizes—that, on the whole, the great religions have been inimical to the free prosecution of scientific inquiry. The folly and wilful deception of the worship of Aesculapius, as its record has reached us, can have been no more helpful to scientific research than any other religious system known to us. Where the Greeks, however, differed from many other peoples is that their priesthood was comparatively weak and divided against itself by the number and variety of their cults, and that their opinions were not reinforced by the study of sacred and canonical books. This gave the philosopher and man of science a freedom of thought and expression which he never experienced again until modern times. That freedom largely explains the success and enthusiasm with which science was prosecuted in remote antiquity. The authors of such Hippocratic works as *The Sacred Disease*, the *Airs, Waters, and Places*, or *Epidemics I and III*, all of which were probably composed in the fifth or early fourth century B.C., were as far removed from the practice of the priesthood of Aesculapius at Epidaurus and elsewhere as are the researches of a great modern physiological laboratory from the practice of Lourdes. Certainly the case for the relation of Aesculapian worship to scientific medicine is no stronger than that which could be and has been made out for modern medicine as a product of Christian thought by pointing out that Nicholas Stensen, whose name is associated with the salivary duct, became a bishop and that several distinguished churchmen, including one pope, have held medical degrees.

Professor Cavvadias junior, in his recent address at the International Congress of the History of Medicine, following his father, who is in agreement with Dr. Withington and the majority of modern medical historians, traced the development of the priestly medicine and the physician's medicine of antiquity along quite separate lines which seldom or never meet. That they may have had a common origin in the natural wonder of man, who always seeks somehow to explain the world in which he lives and to better his lot, all will admit. Few medical men, we think, who take the trouble to peruse the Hippocratic collection and then glance at Dr. Farnell's evidence of the nature and history of Aesculapian worship will be likely to believe in any closer link. But whatever their origin and finer relations no one, surely, will doubt that the main course of ancient scientific medicine was manifestly separate from that of the worship of the god of healing. It is the spirit of Hippocrates and Aristotle, and not that of Aesculapius and Chiron the Centaur, that rules the medicine of our time.

THE INSTITUTION OF THE LEEUWENHOEK VEREENIGING.

The members of the Dutch Cancer Institute held a very successful international conference from October 23rd to 25th at Amsterdam. In the laboratories of the Antoni van Leeuwenhoekhuis, under the presidency of Professor J. Rotgaus, there gathered together a dozen prominent experimenters from England, France, Germany, Austria, Denmark, and Switzerland to discuss the most recent advances made in the experimental study of cancer, and the Dutch are to be congratulated on bringing to the same table men of such different nationalities. The various communications, dealing with the methods of producing cancers, the latent period in the reaction to an irritant, and the analyses of the early and precancerous

changes, will be published in a special commemorative volume, and some will soon appear in our pages. The impetus which these meetings give to experimental cancer research, the interchange of ideas and criticism, and the cordial relations established between the various workers, mark a milestone in scientific endeavour. Future meetings will be held in neutral countries at such times as seem necessary according as researches accumulate. Owing to the charming hospitality of the Dutch, no less than to the excellent scientific contributions, the first meeting will always be memorable. The various representatives agreed to form a society, without definite rules or constitution, which would act as an exchange for original work. Long discussions ensued about the name of the society, till one of the members, a Scotsman who claimed to be a "foreign Dutchman," suggested the title of "Leeuwenhoek Vereeniging," out of compliment to the memory of the illustrious Dutch scientist. We wish it all success.

THE REGULATIONS OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

THE Royal College of Physicians of London has recently made certain alterations in its by-laws and regulations which are of special interest to Members and to candidates for that diploma; one change is of interest to Fellows also. The changes have been duly reported in our columns on October 28th (p. 828) and in this issue (at p. 894); but it seems desirable to attempt to indicate how they will operate. The chief effect of one of the alterations will be to permit a Member to practise in partnership and to buy or sell the goodwill of a practice; he will also be allowed to dispense his own medicines or to make arrangements with a pharmacist to do so. For years past instances have frequently occurred in which a Member has found it desirable to enter into partnership, and it has then always been necessary for him to resign his Membership. Later on he might apply for this to be restored, and it has been the practice of the College to accede to his request unless there was some very good reason to the contrary. In future a Member entering into partnership, disposing his own medicine, or making arrangements with a pharmacist to do so for him will be able to retain his Membership. These restrictions continue to apply to Fellows. A consequential alteration is that a by-law prohibiting admission to the examination for Membership of a candidate who practised in partnership, or dispensed medicine, or made arrangements with a pharmacist to do so has been repealed. This by-law also forbade a Member of the College to be engaged in trade; the exact significance of this is not apparent. Another change has reference to the association of a Fellow or Member of the College with a company or institution having for its object the treatment of disease for profit. In 1888 the College passed a resolution declaring "that it is undesirable that any Fellow or Member of the College should be officially connected with any company having for its object the treatment of disease for profit." The interpretation of this resolution sometimes gave rise to difficulties; the College has now defined its position by adopting the following resolution: "That, subject to the provisions of By-law CXC, it is undesirable that any Fellow or Member of the College should have any financial interest (whether direct or indirect) in any company or institution having for its object the treatment of disease for profit, other than the receipt by him from such company or institution of (1) a fixed salary, or (2) fees, for such services as he may render to such company or institution in his capacity of medical practitioner." By-law CXC, it may be explained, states the powers of the College with regard to Fellows, Members, or Licentiates who have been guilty of any great crime or public immorality, or acted in any respect in a dishonourable or unprofessional manner, or violated any regulations of the College. If the charge be of sufficient importance, and is established, the College has power to withdraw the diploma of the Fellow or Member or Licentiate for a limited period of time, or altogether, as may be determined. It has also power in

minor cases to admonish or reprimand a Fellow or Member or Licentiate, or to inflict a fine not exceeding £10. The College has not arrived, we understand, at the resolution above quoted without long consideration. It was felt on the one hand that it would be most undesirable to interfere with the kind of practice which is now commonly called team work, but on the other that the College could not countenance arrangements under which a medical man had a personal financial interest in the success of an institution of the kind mentioned, since circumstances might arise in which such interests might come into at any rate apparent conflict with his duty as a medical practitioner. Another difficulty the College may experience when interpreting its resolution is with regard to the manner in which such institutions are conducted and advertised. Of this difficulty the British Medical Association has had much experience, in relation particularly to so-called "medical aid institutes." It was found that such institutes were often conducted by their managing committees in such a way as to exploit the medical officers—paying them very insufficient salaries, subjecting them to irritating supervision, and using their names for advertisement. The Association steadily set its face against such exploitation, and after a long and fluctuating fight succeeded in scotching, if it did not completely destroy, the evil. It will be necessary for the College to keep a very close eye on the methods of institutes seeking a richer clientele, in order that any improper tendencies may be nipped in the bud.

ECONOMY AND DISEASE.

WE print elsewhere an abstract of a paper by Dr. R. J. Ewart on the economic factor of the decline of tuberculosis and a report of the discussion which followed. The subject is of immediate interest, and those who have discussed it in the lay press might be likened to the duellists in *Mr. Midshipman Easy*. At one apex of the triangle is the socialist doctrine who will eradicate disease by the instrumentality of a whole-time State medical service, free meals for all, and houses at an uneconomic rent; at another apex gesticulates the "anti-waste" orator, who asserts that if the "public" is only left alone, and does not have to feed and clothe "bureaucrats," it will grow fat and healthy; at the third apex is the more or less gloomy popular eugenicist who favours leaving things to "Nature," but differs from the "anti-waste" exponent in desiring to endow "fit" parenthood. Naturally all those who debated the subject at the Royal Society of Medicine were within the triangle and a long way from any apex of it, for it is plain enough that there is no standing room for an intelligent man on a Euclidean point. Probably the medical man who has turned over the pages of Simon's reports and paid attention to the actual manners and customs of working-class patients now and twenty years ago, will think that Dr. McVail went closest to the root of the matter. The connexion between polluted water supplies and typhoid is obvious now to the densest local authority, and the most parsimonious does not contend that to spend money on pure water is wasteful; certainly not all communities using diluted sewage as a beverage sixty years ago did so because they could not afford anything better. The village of Terling was very poor, which might explain what happened there, but plenty of funds were available for, say, Windsor Castle. The authorities of Windsor Castle and of Terling had the common factor of ignorance; the great sanitarians of the mid-Victorian period had to dispel that ignorance; to do so was a heavy task, but the task was achieved. The men must indeed have a touching faith in the natural good sense of our fathers who suppose that if the money which went in the salaries of Simon, Buchanan, Thorne Thorne, and their fellows had remained in the pockets of the taxpayers, the position with respect to water-borne disease in England would be what it is to-day. Yet it might have been quite easy for a statistician of the late seventies to construct a diagram showing a parallelism between the decline of typhoid and the increase of commercial prosperity in the palmy days of "free trade." Our problems to-day are different in detail but perhaps not in

essence. There are still a few facts respecting health which the man in the street and his local or national representatives do not know; a knowledge of these facts can only be disseminated by a public health service. A wise man will stand within the triangle a long way from the doctrinaire's apex, but not very close to that of the "anti-waste" orator.

THE NATURE OF FILTER-PASSING VIRUSES.

WIDE interest has been aroused in that group of organisms known as ultramicroscopic viruses, or filter-passing organisms, by recent studies in connexion with influenza and by the remarkable phenomenon of bacteriolysis described by Twort and d'Herelle.¹ The considerable list of diseases described in the closing pages of every textbook of infectious disease as of "unknown etiology" is rapidly becoming depleted, the names being transferred to the apparently more creditable position under the heading of diseases due to filter-passing organisms. Influenza and the common cold were the last to make the move; powerful reasons for this transfer were brought forward by Dr. Mervyn Gordon at the Microbiology Section of the Annual Meeting of the British Medical Association, and it should be noted that the ranks of the filter-passing group are thus being swelled by recruits from diseases of bacterial origin also. What then is the nature of the filter-passing or ultramicroscopic viruses? Dr. H. M. Woodcock has made a contribution to the discussion of this problem,² in which he considers the evidence derived from the morphological appearances of these granules when stained by Giemsa's stain. He observes that everything which stains red with Giemsa does not necessarily consist of chromatin, and states that very similar appearances to those seen in smears said to show the filter-passing virus of influenza may result from the degeneration of the nuclei of epithelial cells and leucocytes; his arguments are illustrated by pictures of disintegrating nuclei. He claims to have shown by careful staining that the ultramicroscopic particles do not contain chromatin, for which reason they cannot be regarded as living organisms; and he looks upon them as products of the digestion of organized material. Although Dr. Woodcock does not consider these various bodies and granules to be the actual virus, he thinks a pathological enzyme may be adsorbed on to the granules so that though these granules are not the actual virus they may indicate its presence. In such a disease as influenza an auto-cytolytic action may be set in train, similar to the progressive autolysis observed in the Twort-d'Herelle phenomena, and this auto-cytolytic process may be transmissible through series of animals. It must, however, be said in justice to those who hold that the minute granules are living parasites that their opinion is based on other foundations than those provided by morphological appearances alone. No filter-passing enthusiast would claim that every granule was a living parasite; other origins of these granules are well known, though perhaps insufficient attention has been paid to the derivation to which Dr. Woodcock refers. Therefore, whilst our knowledge of the origin of some of the granules seen in Giemsa-stained films has been made more definite by Dr. Woodcock's work, it cannot be said that he has seriously shaken the contentions of those who look on influenza as being caused by an ultramicroscopic virus.

MEDICAL MEASURES FOR PREVENTING VENEREAL DISEASE.

The committee appointed last April, at the suggestion of Lord Dawson, and with the encouragement and support of the Minister of Health (Sir Alfred Mond), "to consider and report upon the best medical measures for preventing venereal disease in the civil community, having regard to administrative practicability, including cost," is now, we understand, sitting once a week, and has issued a questionnaire to prospective witnesses. It will be remembered that

Lord Dawson's proposal was embodied in two questions. The first was, What, in the present state of knowledge, are the most efficient medical measures for preventing venereal disease? and the second, How far is it ethically justifiable to apply such measures? Lord Dawson suggested that those who had the technical knowledge should get together in conference and try to arrive at conclusions on the medical and administrative aspects of the problem, uninfluenced by any ethical considerations. Until such conclusions, supported by a considerable preponderance of opinion, had been reached it could not, he argued, be reasonably expected that the Ministry of Health should do otherwise than maintain impartiality. When the conclusions were formulated a wider public would decide whether it was ethically justifiable to found a policy upon them. A committee of selection, consisting of eight distinguished members of the medical profession, was appointed, and chose a Committee of Inquiry consisting of fourteen medical men and one medical woman. The names were given in the letter from Lord Dawson published in our issue of April 22nd (p. 655). Afterwards the name of Dr. Morna Rawlins, assistant to the obstetric surgeons in the Department for Venereal Diseases, Guy's Hospital, was added. Lord Trevellyn, who had then recently retired from the office of Lord Chief Justice of England, consented to become chairman, and Mr. T. J. Tomlin, K.C., one of the standing counsel to the Royal College of Physicians of London, vice-chairman. The set of questions the committee has issued to the witnesses it proposes to hear are arranged under three headings: the first heading is as to the nature and efficacy of direct medical measures for preventing venereal infection; the second is as to the treatment and instruction of infected persons as an indirect measure for preventing venereal infection; and the third is as to the administrative measures that can and should be taken for preventing infection. Under the last heading the witness is asked to give an opinion on the efficiency and practicability of instituting measures of immediate self-disinfection, where this should be given, the form it should take, and at what age in both sexes it should be given. An expression of opinion is also asked as to the advisability of continuing the present system of free treatment at public clinics, and as to the propriety of instituting compulsory notification of venereal disease.

THE PLACE OF THE WHITE MAN IN THE TROPICS.

THE question whether the white man can colonize and live permanently in the tropics has often been raised, and much argument has been adduced on both sides. A suitable climate, of course, means one in which he is able not only to live permanently himself, but to beget offspring who will go on living there and who will in turn raise up healthy and vigorous future generations there. Strictly applied, then, in this manner the answer is, No. A strong argument in support of this is the generally accepted belief that the aboriginal inhabitants of the hotter parts of the earth were black and of the colder parts white. Dr. Hewetson, in a very interesting paper read before the Rhodesia Scientific Association at Salisbury last May, surveyed the situation again from the medical and scientific aspects. Amongst medical points he mentioned that miscarriage is more common in white women in the tropics than amongst the blacks and the general birth rate is lower. He agreed with the statement made above, and indeed put it in much the same way. Suitability for living in the tropics, he said, means "the capacity to live in a country and propagate a stock through several generations, as good at least as that from which we sprang." Mere replenishment is not enough. Wherein exactly, he asked, lies the difficulty of Europeans colonizing the tropics? Is it due to germ diseases alone or is the cause climatic, or are both causes operative? There is no doubt that disease does play a part in limiting the activity and life of the white man in the tropics, but there is in addition all those conditions which may be summed up in the word "climate." Dr. Hewetson discussed many of the

¹ BRITISH MEDICAL JOURNAL, August 19th, 1922, p. 259 et seq.
² Journal of the Royal Army Medical Corps, October, 1922.

details embraced in this term. After referring to the influence of the actinic rays on the blood and on the nerves, he denounced in good set terms the dangerous effects of using galvanized iron for roofs and walls, for by them were produced abnormally high temperatures, which caused general weakness, cardiac distress, and paved the way for definite diseases. In addition to those physical effects there are the psychological, which are of the utmost importance: the neurasthenia, the monotony of always seeing the sun, the constant desire for stimulants "to buck one up," the cocktail before dinner to give one an appetite, and so on indefinitely. All the circumstances combine to produce neurasthenia. Dr. Hewetson suggests remedies to meet some of these evils, which seem well calculated to improve the condition and reduce the troubles. He suggests, for example, an absolutely non-heat-conducting roof of asbestos; this, however, would be expensive, and the ordinary thatched roof which the native (taught, no doubt, by long experience) uses for his huts might serve as well. The main factor still remains—the excessive heat—and it is this the white person cannot contend against in the long run. We grumble at the climate of England, but it is the constant changes of weather with the four seasons that harden one and produce the race best suited to inhabit these parts. That is why there are white people here; the excessive heat and constant sun, on the contrary, is why deeply pigmented people inhabit the tropics. We cannot get past this by any argument, however much we would like to do so, as has happened in the Northern Territories of Australia.

OPHTHALMIC PROGRESS IN EGYPT.

THE ninth annual report of the director of ophthalmic work in Egypt, Mr. A. F. MacCallan, shows that there has been further progress in the provision of ophthalmic treatment. The director calls attention to a distinctive feature of the Egyptian ophthalmic hospitals, in that twenty hospitals are grouped under one direction, in which 113,000 new patients were treated, 65,000 operations performed, and over one million out-patient attendances made during last year. He states that this facilitates the systematic trial of various methods of operation and treatment. During last year, of the patients applying for treatment, over 15,000, or 12 per cent. of the total patients, were blind in one or both eyes. Attention is drawn to the distinction between the acute ophthalmias and the chronic disease trachoma. The acute inflammations may, in the absence of treatment, cause blindness in a few days, so severe are they. Chronic trachoma affects some 95 per cent. of the population; it very frequently causes depreciation of vision but loss of blindness. Investigations have been made into the causes of optic atrophy. Last year 114 cases were seen, of which the majority were of the post-neuritic type; most of these followed acute infectious disease, generally typhus, but for the most part it was impossible to determine the cause of the primary atrophy. Investigations into the incidence of glaucoma show that it is more prevalent in Egypt than in other countries, the incidence amongst all patients being 1.77 per cent. as against 1 per cent. amongst Americans. From this disease there arises a serious tale of blindness owing to the late stage at which patients come for treatment. The following regulations have been laid down for the admission of candidates for posts in the Government service: The candidate must have a vision of 6/12 in each eye, or 6/6 in the better and 6/18 in the worse, the error of refraction not to exceed 6 diopters in each eye. If the glasses are stronger the candidate will be rejected unless his physical condition, apart from visual acuity, is above the average.

THE MOTOR SHOW.

THE Motor Show this year, which opened on Friday (the private view was on Thursday), is bigger than ever. Though some firms have not been able to engage enough space to display all the cars they wished to submit to the judgement

of buyers, the number exhibited is so large that the visitor who has only a few hours at his disposal may well feel bewildered. The article on the Show published this week (p. 877) contains details in abundance to enable intending buyers to narrow down within reasonable limits the list of cars they would wish to see as most likely to meet their requirements in respect of construction and price. In addition an attempt is made to estimate the general trend of opinion and new enterprise in the trade. It is satisfactory to be able to draw the conclusion that the trend is towards reduction in price and higher efficiency, especially in the small cars, and a greater disposition to cater for the buyer to whom a car is a necessary part of the equipment for carrying on his business or profession. The growth of the demand for motor cars with an efficient and durable chassis, and comfortable all-weather body, at prices that the man of moderate means who has to earn his living can or ought to afford is being realized, even by some firms which have hitherto looked for purchasers among people with fat purses to whom cars are mere matters of convenience or parade. Medical men now have a long list of reliable cars from which to make their choice.

DELEGATION FROM THE UNIVERSITY OF STRASBOURG.

SEVEN members of the medical faculty of the recently reconstituted French University of Strasbourg have visited the United States, and are now in Great Britain as the guests of the Rockefeller Foundation, the object being to give them an opportunity of studying the organization and teaching methods of American and British universities and medical schools with a view to the coming reorganization of their own university. The delegation will be in this country from October 29th until November 8th. During this time members of the party will study work in their respective subjects at some of the medical schools in London and in the universities of Cambridge, Oxford, and Glasgow; the arrangements are being made by the Medical Research Council on behalf of the Rockefeller Foundation. The party consists of Dr. Georges Weiss, dean of the faculty and professor of biophysics; Dr. Léon Blum, professor of clinical medicine; Dr. Paul Bonin, professor of histology; Dr. Camille Duverger, professor of ophthalmology; Dr. Pierre Masson, professor of pathological anatomy; Dr. Maurice Nicloux, professor of physiological chemistry; and Dr. Lucien Pantrier, professor of dermatology.

SMALL-POX IN LONDON.

LAST week we published Dr. Hamer's report, submitted to the London County Council on October 24th, regarding cases of small-pox which had occurred in Stepney, West Ham, and Dartford. Subsequently the disease was discovered in Poplar workhouse, and Dr. H. A. Macowen of the Ministry of Health at a meeting with the Board of Guardians reported that some twenty cases had occurred and been removed for isolation. On October 31st the Poplar medical officer reported five more cases, all in the workhouse. The diagnosis of all the cases as they arise is being reviewed by Dr. Wanklyn, of the London County Council. Many of the cases are of severe type. The workhouse outbreak need not create great alarm. In such an institution every individual, whether inmate or officer, can easily be kept under observation and dealt with as may be advisable. We have no doubt that the guardians are in this matter accepting the advice of Whitehall as to vaccination, isolation, and surveillance of contacts. The five new cases reported on October 31st would belong to the first crop from the original source. The object now must be to prevent a second crop, and that, we trust, will be, in the circumstances of the workhouse, successfully accomplished. The more alarming fact is the appearance of the disease in so many different localities—Stepney, West Ham, Dartford, and Poplar—and also the circumstance that confluent cases are included in the outbreak. To search for contacts in these crowded populations,

with the class which they include, cannot but be a difficult matter, and the outcome will be watched with some anxiety. Meantime the prudent should make certain that they and their children and dependants are secured against the infection by immediate vaccination. Why the public vaccinator did not take care that he himself was protected is the most puzzling thing in the whole outbreak.

HUXLEY LECTURE.

Owing to the indisposition of Sir Arthur Keith, F.R.S., the Huxley lecture which was to have been delivered at Charing Cross Hospital Medical School on Wednesday next, November 8th, has been postponed.

THE new x-ray department of the Manchester Royal Infirmary will be formally opened on Friday, November 18th, at 2.30 p.m., by Sir Humphry Rolleston, who, with the members of the Electro-Pathological Section of the Royal Society of Medicine and the Röntgen Society, will be visiting Manchester.

THE GENERAL ELECTION.

The position of parties at the approaching General Election is confused. The Conservative Party (C.), also spoken of as Unionist (U.), and the Labour Party (Lab.) have been before the constituencies for a good many years, and their position is fairly well defined. In addition there is the Liberal Party, which seems to be divided into two wings, one led by Mr. Asquith (L.) and the other by Mr. Lloyd George, which is known as the National Liberal Party (N.L.).

The following is a list of medical candidates so far as we are at present able to ascertain. We shall be glad to receive additions and corrections.

- *Dr. C. Addison (L.), Shoreditch
- Dr. R. Ambrose (Ind. Lab.), Whitechapel
- Dr. H. Wausey Bayly (Ind. U.), Sutton, Plymouth
- Dr. H. B. Bates (U.), Newton, Lancs.
- Dr. Ethel Bentham (Lab.), Islington East
- Sir George Berry (U.), University of Edinburgh
- Dr. I. Walthamstow East
- Dr. J. ies
- *Dr.
- *Dr. Albans
- Dr. uthwark North
- Mr. (Lab.), Epsom
- Dr. C. W. Hayward (L.), Kensington North
- Dr. Sidney C. Lawrence (C.), Combined English Universities
- Dr. H. D. Levick (N.L.), Middlesbrough
- Sir William Milligan (L.), Salford West
- *Major J. E. Molson (U.), Gainsborough
- Dr. R. O. Moou (L.), Wimbledon
- *Dr. H. B. Morgan (Lab.), Camberwell North-West
- *Dr. D. Murray (L.), Western Isles
- Sir Sydney Russell-Wells (U.), University of London
- Dr. V. H. Rutherford (Lab.), Sunderland
- Dr. A.
- Dr. R. upon-Tyne North
- Dr. Ge. West
- Dr. E. H. Stancombe (Ind.), Southampton
- Dr. D. F. Todd (U.), Chester-le-Street, Durham
- Dr. T. Watts (U.), Withington
- *Sir William University, Belfast
- Dr. J. H.
- Dr. R. M.

*Represented the constituency in the last Parliament.

Among the new candidates Dr. H. B. Brackenbury (Walthamstow East) and Sir Sydney Russell-Wells (University of London) have been approved by the British Medical Association. Among the old members who are standing again are Sir Henry Craik (Scottish Universities), Sir William Whitla (Queen's University, Belfast), Dr. Walter Elliot (Lanark), and Dr. F. E. Fremantle (St. Albans); all of them have done yeoman service in the House of Commons for the profession, and have frequently given assistance to the British Medical Association in representing the views of the profession to Parliament.

British Medical Association.

COUNCIL DINNER.

THE British Medical Association made a departure on October 25th by the inauguration of a Council dinner, which it is intended shall be an annual event. It is designed for recognition of the Past President and any other retiring officer at the end of his term and to bring together, in converse with the Council, Ministers, the heads of learned societies, and others with whom the Association is in touch.

The dinner took place at the Grand Hotel under the chairmanship of Dr. R. A. BOM, Chairman of the Council, who explained that, owing to the political crisis, several Ministers (who had accepted invitations) and a number of members of Parliament had other more pressing engagements and had sent letters of regret.

The following guests of the Association were present:

Professor David Drummond, C.B.E., D.C.L., retiring President; Right Hon. E. Shortt, K.C., M.P.; Sir Humphry Rolleston, K.C.B., President, Royal College of Physicians of London; Sir Anthony Bowlby, K.C.B., K.C.M.G., President, Royal College of Surgeons of England; Sir William Hale-White, K.B.E., President, and Sir J. Y. W. MacAlister, Secretary, Royal Society of Medicine; Surgeon-General W. B. Slaughter, Master of the Apothecaries' Society; Lady Barrett, C.B.E., President, Medical Women's Federation; Sir Arthur Robinson, K.C.B., First Secretary, Ministry of Health; Sir George Newman, K.C.B., Chief Medical Officer, Ministry of Health; Right Hon. Sir Henry Craik, K.C.B., LL.D., M.P., Sir Philip Magnus, Bt., M.P.; Dr. W. J. Howarth, Past President, Society of Medical Officers of Health; Dr. J. G. Fitzgerald, Chairman of Council, Irish Medical Schools' and Graduates' Association; Dr. C. Hubert Bond, Commissioner, Board of Control; Air Commodore D. Munro, C.I.E., Director, R.A.F.M.S.; Lieut.-Colonel Nathan Raw, C.M.G., M.P.; Sir S. Squire Sprague, Editor of the *Lancet*; Sir William Gyn-Jones, Secretary, Pharmaceutical Society.

Sir WILLIAM MACEWEN, President of the Association, in giving the toast, "The Common Health," said that when he wired acceptance of the duty the telegraph clerk interpreted the words in his handwriting as "The Common Wealth." That man was a philosopher, for wealth was to a large extent a matter of health. Many persons very wealthy, in the ordinary acceptance of the term, were not healthy. Gold often produced decadence. He understood that the permanent secretary to the Ministry of Health would respond to the toast, and he assumed that the responsibilities of this Department embraced everything. Our old world (which was a kind of aeroplane), when it went gyrating through space, picked up dust storms that astronomers said were got from sand, and, although these particles were so finely divided that there was not an instrument sufficiently intricate to detect them, yet the Ministry of Health must have prescience to foretell what would come from them. So also as to those little canisters containing chemical substances labelled "wild duck"; from them they were expected to trace botulism. He did not know where investigation was going to stop. They all ought, however, to look to several matters about which they had common concern. The Association had especially to consider two very prevalent diseases regarding which certain theories had been formulated and put before the public, and a very great deal would be done if they could be got rid of. One was syphilis; the other tuberculosis. As to the first named, if it were not stopped, a crime was committed against posterity. The question was sometimes asked, "Where to draw the line?" He drew no line: the disease must be got rid of by whatever means were necessary. Tuberculosis was not so easily dealt with. But the profession had a great responsibility. If the British Medical Association, with its 25,000 members made up its mind as to the means it would carry great weight. He wondered whether the medical profession had not hitherto just relied upon polemical discussions instead of pushing matters to logical conclusions and then pressing them upon the Government and the officials who had to carry them out. Much of this disease, it was said, came from cows through milk, and about 50 per cent. of the tuberculosis in children was bovine. If so, how did it come from the cow? Surely it must be through the milk. Tubercle was incubated in byres as directly as in an incubating chamber. The best temperature in which to keep cows, it was said, was 70°F., and in byres were found the three other conditions in which tubercle easily propagated itself—namely, darkness, dirt, and damp. From such places, in such

conditions, came milk given to children. Surely, if 25,000 medical men acted in concert some action might be taken to end that form of tuberculous disease. And if they got rid of 50 per cent. of the disease that way they ought to be able to get rid of a good deal that came by transmission from one person to another. Sir William Macowen went on to remark that the British were a strange people. They taxed the air they breathed. Formerly they used to tax the light which came into the houses through the windows. Now, in effect, the cubic capacity of houses was taxed. God had given every single soul that came into the world as much air as it could breathe, but it was curtailed in this way. Those who got tubercle from confinement were put into sanatoriums where they could get just the fresh air God had given. Would it not be better to commence the other way and give the children and others as much fresh air as they could breathe? These were points which required consideration, and he thought it a good thing to ventilate them on that occasion. He coupled with the toast the name of Sir Arthur Robinson, First Secretary of the Ministry of Health (paying high tribute to the permanent civil servant whose work continued while Ministers came and went), and he also associated with it the name of Sir Anthony Bowlby, President of the Royal College of Surgeons, who did much good service at the front, and whose methods were a little more direct.

Sir Arthur Robinson hoped he would be in order in offering an expression of sympathy with the company. Instead of the solid substance of a Minister of the Crown they had to be content with the pale and embarrassed shadow of a permanent civil servant cast for a somewhat unwanted task. However, replying to such a toast as the Common Health was one that should inspire even a silent civil servant to something rather above than beyond his ordinary performance. Sir William Macowen had said that it was time that something was done in regard to the milk supply. Well, the Department had put on the statute book a measure which, though not heroic or final, would be valuable. The underlying principle was to make it worth while to supply better milk. Provide a man with inducements to supply good milk and it was common sense to suppose that he would do so. He could say also as to tuberculosis that there was a policy. It had its limitations, but by reason of it the notifications had gone down and were going down, and the death rate had gone down and was going down. Speaking generally, Sir Arthur Robinson said that the Ministry of Health had been in existence only a short time and had done a great deal. Something like 200,000 houses had been or were being built, and nothing like that had been done before through a department. The Ministry had also made a fair start in dealing with the problems of slum areas. Then there was the question of the voluntary hospitals. In a period of unexampled difficulty they had prevailed on the Government to give a sum of half a million sterling to set going machinery which was gradually bringing the voluntary system round, and it had made possible the continuance of the voluntary system in fact and not merely in name. Broadly, the problem of public health seemed to him one of fitting various parts into a whole. It was a problem of mutual tolerance, of mutual forbearance, and of working together for one end. Unless they did this on the basis of giving each element in their policy full weight the policy would be wrong. The Ministry of Health presided over the whole public medical health service. It was in close relations with the whole mass of general practitioners through the insurance services. There they had a body which dealt with private persons and with public health, appreciating the different view-points and getting progress by unity. He appealed for the co-operation of the medical profession as represented by the British Medical Association.

Sir ANTHONY BOWLBY said he represented one of the two English Royal Colleges concerned with the education of medical men. In this connexion the Colleges did two things—they examined and they set the pace (the curriculum) for the different medical schools of the United Kingdom. During the year the two Colleges had spent much time in rearranging the curriculum, the main object being to give more time to the most important subjects—those in the final examination. The task of the present-day student was very difficult. That individual, he rather thought, looked upon the whole performance from the point of view of an obstacle race. The student saw in front of him a long way off—five or six years distant—the winning post. In an obstacle race all sorts of things were put in the way of a competitor to delay him. The student found the biology examination to begin with.

Then came the chemistry and physics people, who might put up a better barrier, and sometimes succeeded. After the next obstacle—anatomy—came a greater, physiology. For whereas anatomy was a fairly accurate science, and the femoral artery of to-day was very much where it was a hundred years ago, the physiology of to-day was quite a different thing. Twenty or thirty years ago they thought they knew something about the processes of digestion and the action of the heart and respiration, but it now appeared that they did not. So there was reason to pity the poor candidate. Having surmounted these obstacles he entered upon the last lap. This used to comprise medicine and surgery and obstetrics. Now innumerable special subjects were added, so that one might wonder and think how "still the wonder grew that one small head could carry all he knew." It was indeed a severe task; yet, in spite of the difficulty of seeing the wood for the trees, in spite of the fact that a large number of young men know a great deal about abstract and special subjects without knowing much about general practice, in the long run the educated medical man of the present day was a strong stand-by and supporter of the public health of this country. Finally the young man became a full-blown medical practitioner, and then he sought the advice of those in practice. One piece of advice he would give to every young medical man, and that was to join the majority—not in the proverbial sense, but to join the majority of the profession, the British Medical Association. They would thus get in touch with their fellows—an important matter in the medical profession—and would have assistance and advice when necessary from older members. If the newly qualified men went into any of the services, there was still another reason why they should join the Association. In recent years the action of the British Medical Association had obtained great benefits for the Army and Navy Medical Services, the Indian Medical Service, and the Colonial. In all these departments the Association had been of very great assistance to medical men, and he hoped as in the past, so in the future, a very large number of qualified men would become members.

Dr. R. WALLACE HENRY gave "The Retiring President," and said that for many years it had been the custom for the President to enter upon his term of office in a blaze of glory. He had given his presidential address surrounded by civic dignitaries and distinguished men of science, clad in garments of many colours. But he had gone out of office so quietly that it might almost be said he was "unwept, unhonoured, and unsung." This year the Council had decided that such practice should come to an end, and that each year a dinner should be arranged at which one of the principal toasts should be "The Past President," and in paying tribute that night to Professor Drummond they were making a start with one whose name would rank high amongst the eminent men who had held that office. It was many years since he left his native land of Ireland, and at a very early period of his professional career Professor Drummond began to make his mark. He had the opportunity at the Meath Hospital at Dublin of working under that distinguished heart physician, Sir William Stokes, one of whose favourite house-physicians he was, and what he learned and studied there he took into his private practice when he went to the north of England. He wrote many articles dealing in various aspects with his favourite subject (heart disease), one in particular on aneurysms of the thoracic arch. But his studies were not confined to the heart. He turned his attention to nervous diseases, and one of his works was a standard book upon diseases of the brain and the spinal cord. His reputation in Newcastle rapidly grew, and he became physician to the Royal Victoria Hospital. His reputation spread abroad. He had received many distinctions from foreign countries. It was not true in his case that the prophet was without honour in his own country, for he had been made Principal of the College of Medicine at Durham University as well as Professor of Medicine there, and now held the post of Pro-Vice-Chancellor of that University. Last of all, within the past two months, appreciation of his services in Newcastle-on-Tyne had been marked by his being appointed Chairman of the Voluntary Hospitals Committee of that area. So much in brief for his purely professional work. In the British Medical Association he must be one of the oldest members: he had been enrolled forty-four years. As had been the case with a very large number of students at Dublin University and at Queen's College, Belfast, it had been preached to him and his colleagues that almost as soon as they had qualified one of their first duties was to join the British Medical Association. Would that the same thing could be done at all the universities in Great Britain also!

Professor Drummond had been formerly a member of the Council of the Association, had been Secretary of the North of England Branch and at one time President, and it was partly due to his work in connexion with these offices that the Branch held such a distinguished place in the Association for the splendid work it had done. They would drink his health, not merely as a great physician, but merely as Past President of the Association, but also as "David Drummond the man." They all regarded him with affection and esteem.

Professor Drummond said it was a great pleasure to him to meet so many distinguished colleagues; and this was enhanced by the fact that he was the recipient of their hospitality on the occasion of the inauguration of a function which he hoped had come to stay. He went on humorously to depreciate the tribute just paid to him by Dr. Henry as the general compliment of one Irishman to another, and then spoke of the great interest of the period—three years—of his official connexion with the Association as President-elect, President, and Past President. The Annual Meeting formed a very important part of the proceedings, and their meetings at Cambridge, Newcastle-on-Tyne, and Glasgow had been held to be as successful as any they had had for many years. In recalling the gathering at Cambridge he evoked applause by referring to the great personality of the great President of the year (Sir Clifford Allbutt).

The CHAIRMAN submitted the toast of "The Visitors," very happily referring to their widely representative character and expressing the hope that from year to year they would have present, amongst others, the Ministers with whom they dealt in other circumstances, perhaps not quite with the cordiality with which the welcome was given that night. He entirely agreed with Sir Arthur Robinson, that these meetings would promote in every way friendship and co-operation, than which nothing was more needful to the country in these years of strain. Coupling the toast with the names of Mr. Shortt and Sir Henry Craik, the Chairman spoke of the sympathy which Mr. Shortt had manifested as Home Secretary for their work, and expressed gratitude to Sir Henry Craik for wise counsel and kindly help in his capacities as an experienced parliamentarian.

Mr. SHORTT, replying in light vein, questioned whether he ought to be there, as the invitation had come to him when he was Home Secretary, but he assured the company that he had greatly enjoyed the evening, and also touched on the satisfaction of being relieved from the cares of office. A Home Secretary who tried to do his duty made enemies every day of his life. Everything he did annoyed somebody, and those who were pleased with what was done generally took it as a matter of course.

Sir HENRY CRAIK said that for seventeen years the medical profession had tolerated him as a humble representative in Parliament of twelve thousand of their members. The British Medical Association had conferred upon him the great honour of making him an honorary member of their society, and they had further gratified him by admitting him to their counsels. He had learned much thereby. He recognized that the two great objects for which the Association lived were the maintenance of scientific truth in its highest form and the pursuit of research for the good of mankind. He had found also that, according to the scriptural phrase, truth was joined with mercy. The maintenance of the kindest relations between the great medical services and those whom they served was the principle upon which they lived, thrived, and did their work.

Sir JENNER VERRALL submitted the health of the Chairman, speaking in the highest terms of his qualities, and the toast was received with musical honours.

Dr. BOLAN, responding, said that this toast was given against his ruling. Service for such an Association was a great privilege, and he was happy in performing it.

THE Loomis Sanatorium, New York, has recently celebrated its twenty-fifth anniversary, and has published in commemoration a "birthday book," giving a description of the foundation, the growth, and the progressive enlargement of the institution. A special block has been erected at the expense of the Standard Oil Company for the treatment of its employees. In formally handing this over to the sanatorium, the vice-president of the company suggested that this course might well be followed by the other large commercial houses of the United States, for not only would the treatment of tuberculosis be better carried out, but the cost would be less if borne by private firms than if controlled by the Government.

Scotland.

PARLIAMENTARY REPRESENTATION OF UNIVERSITIES.

It is thought improbable that there will be any contest this general election for the representation of the Scottish Universities in the House of Commons. There are three seats; Sir Henry Craik and Mr. Cowan are standing again and Sir George Berry, consulting ophthalmic surgeon to the Royal Infirmary, Edinburgh, is offering himself in the place of Sir Watson Cheyne, who decided some time ago not to seek re-election.

BOTULINUS ANTITOXIN.

In view of the recent outbreak of botulism at Loch Mar the Scottish Board of Health has under consideration arrangements to render available a supply of botulinus antitoxin in the event of the occurrence of any further cases in Scotland. There is no reason at present to expect further outbreaks, but the gravity and mortality of the disease may be such that it is considered that arrangements should be made to provide a supply of antitoxin which could be obtained more promptly than if the only available supply were held in London or Edinburgh. It is pointed out that the only remedy at present known for botulism is botulin antitoxin given by injection, but that it is unlikely to save life if the disease has progressed to a late stage. It is therefore of the greatest importance to give the antitoxin at the earliest possible moment—that is to say, as soon as symptoms of blurred or double vision, giddiness, ptosis, difficulty in speech or swallowing, suggest the diagnosis of botulism. The effectiveness of treatment by antitoxin in this disease is so greatly increased by intravenous injection that this method of administration should always be employed, if possible; otherwise the intramuscular method should be used. It may be necessary to administer subcutaneously a preliminary injection of a small quantity of the antitoxin (0.5 c.c.m. of antitoxin, or 8 minims) to test the reaction of a patient, in order to avoid the risk of serious symptoms arising in persons highly sensitive to horse serum. If the patient is sensitive the antitoxin must be given with caution, and the dose should be considerably reduced, the first intravenous injection of 0.5 c.c.m. of antitoxin being diluted with 50 c.c.m. of saline. Only large doses of antitoxin will save acute cases; the ordinary intravenous dose should be from 20 to 50 c.c.m. of the antitoxin; it should be previously warmed to body temperature and injected very slowly. This amount may be repeated daily if necessary. On the occurrence of an outbreak of botulism it may be deemed necessary by the medical attendant or the public health authorities that all persons who have consumed the suspicious food should be given a prophylactic dose of antitoxin (10 c.c.m. intramuscularly) even though they may not present symptoms of the disease. The Board of Health has accordingly made arrangements for a small stock of the antitoxin to be kept at the following places, as well as the offices of the Board in Edinburgh: the City Hospital, Aberdeen; King's Cross Infectious Diseases Hospital, Dundee; City Hospital, Edinburgh; Belvidere Hospital, Glasgow; the medical officer of health, County Buildings, Dumfries; Mr. Macdonald, Mayor's Drug Store, 31, High Street, Inverness; and the County Hospital, Motherwell, Lanarkshire.

THE GRADING OF MILK.

The Milk and Dairies (Amendment) Act, 1922, authorizes the Scottish Board of Health to make an Order in regard to licences for the sale of graded milk. The Board has no issued, to producers of higher grade milk and others, memorandum showing the principal conditions under which the statutory Order will be made. Before issuing this the observations of those interested were invited. The Milk and Dairies Act, 1922, contemplates four grades of milk in Scotland—namely: (1) certified milk; (2) grade A (tuberculin tested) milk; (3) grade A milk; (4) pasteurized milk. It is proposed that the administration in regard to all four shall be placed in the hands of local authorities under the Public Health (Scotland) Act, 1897.

Certified Milk is milk obtained from tubercle-free cows at bottled at the farm.

Grade A (Tuberculin Tested) Milk is the same as Certified Milk except that it is not bottled at the farm.

Grade A Milk is milk obtained from herds which have been examined at least three times a year at the farmer's expense by a veterinary surgeon, but the examination will not include tuberculin tests.

No particular make of pasteurizer is prescribed, but the milk must be retained at a temperature of not less than 145° and not more than 150° F. for at least half an hour, and immediately cooled to 45° F. This condition applies to milk sold under the designation "pasteurized." Tuberculin tests for the first two grades will be carried out at the expense of the farmer. A score card inspection will be made by the local authority in connexion with certified milk, and annual fees will be payable in respect of all grades, in order to cover some of the expenses incurred by local authorities. Milk which is delivered to the consumer, must not contain more than a specified number of bacteria.

UNIVERSITY OF EDINBURGH GENERAL COUNCIL.

While the subject of exclusively medical interest engaged the attention of the General Council of the University of Edinburgh at its statutory half-yearly meeting on October 26th, in several matters medicine had an important stake. It was so, for instance, in relation to the draft of regulations for the preliminary examinations which had been drawn up by the Scottish Universities Entrance Board. It is pointed out by the Rev. Professor W. P. Paterson that a language was compulsory among the subjects of examination, but that there was no compulsion that this language be Latin; this would be a blow to Scottish culture. Sir Richard Edgo stated, in reply, that the inclusion of compulsory Latin would be inconsistent with uniform admission to all faculties; that Latin as a subject could be imposed by the University in connexion with particular classes and was not barred. Approval was given of the draft regulations. Principal Alfred Ewing, who presided, supplied the matriculation figures up to the preceding day (October 26th), and compared them with the completed figures for 1921-22; they were as follows:

	1921-22.	1922-23.
Arts	1,574	1,548
Science	974	742
Divinity	75	64
Law	193	172
Medicine	1,838	1,403
Music	10	18
	4,669	3,952

GLASGOW AND WEST OF SCOTLAND OVERSEAS MEDICAL CLUB.

The annual dinner of the Glasgow and West of Scotland Overseas Medical Club was held on October 27th in the Grosvenor Restaurant, Glasgow, when the president, Dr. J. Livingstone Loudon, T.D., officiated as chairman of a representative gathering. The president and secretary of the club in the east of Scotland, Mr. H. Wade, C.M.G., S.O., and Mr. W. T. Gardiner, M.C., were present as guests of the club. As on former occasions, the opportunity for the renewal of old service associations was much enjoyed, and musical entertainment provided by Drs. T. D. Laird, Wallace Anderson, C. G. Macartney, J. Scouler Buchanan, and T. Gardiner was duly appreciated.

CENTRAL MIDWIVES BOARD.

At a special meeting of the Central Midwives Board for Scotland for the hearing of penal cases, with Dr. James Craig Ferguson in the chair, a certified midwife was cited to appear in respect of failure to notify contact with a person suffering from puerperal fever, thereby endangering the lives of her other patients, and for other breaches of the rules. The Board found the charges to be proved, and instructed the secretary to cancel her certificate and to remove her name from the Roll.

Victoria.

AUSTRALASIAN MEDICAL CONGRESS, 1923.

Presidents of Sections in connexion with the first Australasian Medical Congress, organized by the Branches of the British Medical Association in Australia, have now been finally appointed, as follows:

Medicine.—Dr. W. Marshall Macdonald, Dunedin.

Surgery.—Mr. R. Gordon Craig, Sydney.

Gynaecology and Gynecology.—Dr. J. A. Cameron, Ipswich.

Pathology and Bacteriology.—Professor J. B. Cleland, Adelaide.

Preventive Medicine and Tropical Hygiene.—Dr. F. S. Hone, Adelaide.

Ophthalmology.—Mr. D. D. Paton, Perth.

Otology, Rhinology, and Laryngology.—Dr. T. S. Kirkland, Sydney.

Neurology and Psychiatry.—Dr. A. W. Campbell, Sydney.

Diseases of Children.—Dr. R. B. Wade, Sydney.

Naval and Military Medicine and Surgery.—Colonel W. W. Giblin, Hobart.

Dermatology.—Dr. R. E. Harrold, Adelaide.

Radiology and Medical Electricity.—Dr. Valentine McDowall, Brisbane.

As a preliminary step to the election of Presidents of Sections the Branches of the British Medical Association in the various States of Australia and New Zealand were invited to forward nominations, and from these the above were finally appointed by the Executive Committee of the Congress.

The meeting will be held in Melbourne in November, 1923, under the presidency of Mr. G. A. Syme, and any members of the British Medical Association resident in Great Britain and Ireland who may find it convenient to attend will be very cordially welcome. The general secretary is Dr. A. L. Kenny, 13, Collins Street, Melbourne.

POST-GRADUATE WORK.

Encouraged by the great success of, and the large attendances at, the recent series of post-graduate lectures on the nervous system and its diseases, the Melbourne Permanent Committee for Post-graduate Work has organized a second series on obstetrics, to be held at the Women's Hospital in September and October. This series is being specially conducted in connexion with the examinations for the degree of Doctor of Medicine, University of Melbourne.

THE NEW ANATOMY DEPARTMENT OF THE UNIVERSITY OF MELBOURNE.

The new anatomy department, designed to accommodate 600 students, was commenced in January, 1922, and is making fairly rapid progress. The building is in brick, with stone facings, and is Tudor in type. There are two dissecting rooms, each capable of accommodating 300 students, a large and well-lit museum, a theatre to hold 300 students, reading rooms, cloak rooms, and retiring rooms for men and women students. On the entresol floor, between the two dissecting rooms, are the private rooms for the staff, so placed that they command both dissecting rooms. On the upper floor there is a large and well-lit histology laboratory, capable of accommodating 250 students, together with private rooms and research laboratories for the histology staff. There are in addition rooms for operative surgery, neurology, and physical anthropology, and museum preparation rooms, with ample provision for the preservation of subjects and the storage of anatomical material. A special feature of the building is the flat roof over the histology department, from which will be obtained a magnificent view over Melbourne and Port Phillip Bay. There can be no question that the new building will prove of great utility to the University and the medical profession, and will be a decided acquisition to the City of Melbourne. Its utility would have been considerably enhanced had the University council carried out its own resolutions of 1914-15 and erected the building—in accordance with the unanimously expressed wish of the profession—alongside a hospital, instead of within the University grounds. In 1914 the whole medical school could have been re-erected alongside a hospital for about £30,000 more than the present building actually cost (that is, for £100,000) as against the present estimated cost of £70,000 for the anatomy department.

Paris.

[FROM OUR CORRESPONDENT.]

WITH October the official medical life begins again. Our faculty has not yet opened its doors to the young students, but they have already been opened to the old students—we practitioners who have flocked to certain congresses in Paris.

French Congress of Surgery.

To take the national congress of surgery first; at this annual meeting the surgeons of the whole of France are brought together in Paris. This year Professor Hartmann was president. Without entering upon a critical review of the proceedings of the congress, I would emphasize one fact that must strike every spectator—the position occupied by the younger generation of surgeons. They have been formed by the war. They were then called upon to play the part of

chefs de service in departments where activity was unprecedented. They have learned to accept responsibility. They have found themselves! It is not surprising therefore that they took a large share in the work of the congress and presented many communications and contributed to the discussions concise, short, and lively remarks in the true surgical manner. We have in this a remarkable evolution; the after-war spirit has smashed the old surgical machine—its traditions, its hierarchy, and its methods. Is it a gain? There are always two sides to a question.

There is only one incident to note. The president refused to allow Dr. Voronoff to read his paper on rejuvenation by glandular grafts. The reason was that the lay press on that very morning had trumpeted forth a hymn of praise to the glory of the method and its inventor. The result is that Dr. Voronoff has had to continue as he began, and it is in the daily papers that we have read about the super-magnificent results of the grafting of the testicles of the chimpanzee into old men. You may guess whether writers of gossip and caricaturists have hesitated to profit from such a subject! May someone perhaps succeed in grafting the brain of a fox—and wisdom—under the human skull?

Congresses of Medicine and of Urology.

The congress of French-speaking physicians followed, under the presidency of Professor Vidal. For long he has been a man of mark, owing to his scientific renown, his personal authority, and the charm of his easy speech. The mantle of his master, Dénlafoy, has fallen upon him. No one knows better than he how to guide a discussion, how to keep the main point in view, and how to sum up a question in a few decisive words. The subjects of discussion were the eternal question of ulcers in the neighbourhood of the pylorus and the new problem of deficiency diseases, looked at from the point of view of their treatment. Much has been said, but we are left with the impression that much remains still to be said! At the twenty-second French Congress of Urology, which was held at the same time, there was an interesting discussion on diverticula of the bladder.

Examinations for Resident Hospital Posts.

The competitive examinations are also starting again. As I have already explained (JOURNAL, January 7th, 1922, p. 32), the examination for resident hospital posts was completely changed two years ago, by the introduction of the principle of anonymity in the preliminary written examination. The candidate has to answer in a very limited time numerous questions bearing upon very precise points of anatomy. He is not asked for phrases, but for facts, and this enables the judges, by a simple process of marking, to award points which determine the classification of candidates and the rejection of those found unsuitable. Much was expected from such a simple and just method. There has been a great disillusion. The reason why we now see the most ardent of its promoters disenchanted is that, the test being solely a test of memory, the youngest candidates, fresh from the anatomy classes, have been greatly favoured. On the other hand, the older candidates, who, though they had gained in clinical experience, had lost in memorized scientific knowledge, have too often failed. Now the resident house-physician is called upon to become the right-hand man of his chief, and this requirement cannot be fulfilled by too young a student who nevertheless wins a usurped title. In the long run it is our patients who suffer from it, and so we have the whole question *sur le tapis* again. It is less a question of recognizing what a man knows than what he is, and anonymity, so far from being the *summum jus*, seems an unwise expedient at the first stage of the competitive examination.

Problems of the Medical Students.

It is further to be said that even the recruiting of students is difficult. Nowadays it is impossible for a medical student to begin his studies unless he has sufficient private means. It is calculated that a student cannot cost his family less than £200 a year—at the present exchange, 12,000 francs. Such a sacrifice cannot be expected from the families of professors or from those belonging to the professions commonly called liberal. The students tend, therefore, to come from business circles, and naturally to have quite a different spirit. So much money invested in studies must show financial returns, and even the belief in a professional vocation will soon have gone. This is a social danger that an increase

in the number of scholarships could have avoided; but the general public does not yet understand.

The future of our medical schools must cause much anxiety. Already we are isolated as a nation. The countries with low exchanges can no longer send us students. We, ourselves, can no longer dream of visiting your teaching centres or those of America. To buy an English book seems an act of madness when as it is our students can no longer buy the textbooks they require. The world has already experienced epochs of regression.

Correspondence.

POST-GRADUATE COURSES.

SIR,—In reply to the letter by "Ambitious" (October 28th, p. 827), may I point out that the problem of post-graduate study in the provinces is being rapidly solved along the lines he suggests? Under the scheme initiated by the University of Bristol, courses of study have been or are being held at Hereford, Trowbridge, Swindon, Bournemouth, Barnstaple, and Dorchester. The initial steps have been generally taken by the local Branch or Division of the British Medical Association, which forms a small subcommittee of management. Application having been made, the University sends a circular to all medical men in the immediate vicinity of the proposed centre. This circular gives full details of the proposed course of study, time and place of meeting, etc. The subjects of the demonstrations have generally been selected by the subcommittee from a long list supplied to them by the University. The meetings are usually held in the late afternoon, and always at the local hospital. They are carried on by a lecturer selected by the post-graduate committee of the University, who visits the centre one day a week.

In some towns in the West of England where there are large hospitals which are not, however, teaching schools, the procedure is somewhat different. Either the neighbouring practitioners are invited to join in the medical and surgical rounds on one particular day of the week, or post-graduate lectures and demonstrations are given by the members of the honorary staff, with any such outside help as may be needed. In the Supplement of October 28th (p. 163) it was announced that such a course is to be held at Plymouth, beginning on November 8th. Such a plan as the above can be carried out in any district within a few hours' journey of a medical teaching centre, and if any difficulty in obtaining facilities arises application should be made to the Science Committee of the British Medical Association, which has now taken over the duties of the old post-graduate committee.

In conclusion, may I say that such courses cannot be made free, as "Ambitious" suggests. There are expenses of advertising, postage, hire of room, etc., and it is only just that the lecturers coming from a distance should be paid a small fee and their travelling expenses. In the West of England the attendance on such demonstrations has been so good that the subscription can be fixed at about two guineas.—I am, etc.,

J. ODERY SMYTH,

Chairman, Medical Post-graduate Committee,
University of Bristol.

Bristol, Oct. 30th.

X RAYS IN HYPERTRICHOSIS OF THE FACE.

SIR,—The selective and permanent destruction by x rays of normal hair follicles, without damage to other structures in the skin, is at present a technical and histological impossibility.

The assertion is dogmatic, but will not, I think, be challenged by any of my dermatological colleagues, none of whom, to the best of my belief, have ever advocated this treatment in uncomplicated cases of facial hirsuties. That it is, however, being practised in certain quarters is evidenced by the fact that I was recently consulted by a lady who had been receiving the treatment in London (incidentally, without benefit) for the past eighteen months. The operator in this case presumably knows the risk he is running, and my protest is not so much directed to him as to the general medical practitioner, who may in the future be approached and persuaded by his patients to allow them to submit themselves to radiotherapy for hirsuties, because "their friend Mrs. — was cured in a pleasant and painless fashion."

The following case, at present under my care, illustrates

with remarkable fidelity to textbook description all the risks that the procedure may entail:

The patient, a nursing sister, in June-July, 1911, received, without medical authority, twelve doses of x rays at weekly or ten-day intervals for hirsuties of the face. The operator, who is known to me as a person of great experience and ability in this line of work, assures me that at the time there was no undue reaction or irritation, and both she and my patient are in agreement that the epilation was successful and satisfactory in every way. There has been no regrowth of the hair in the eleven and a half years that have since elapsed, but in June, 1914—*exactly three years after the first session*—"small red spots, resembling the moel that are seen in babies," began to appear on the chin, and these have gradually spread to the cheeks and neck until, as at the present time, the whole chin, the mandibular area, and the anterior and lateral cervical surfaces are covered with these vascular points, while the skin itself is atrophic, dry, and scaly, and exhibits a patchy alteration of the normal pigment distribution, being a papyry white in some places and hyper-pigmented in others.

Subjectively there is "severe irritation, especially at night," a pricking sensation like hot needles," and a dry feeling of the whole irradiated areas, "as if the sweat glands had been destroyed"—as in actual fact is the case.

In brief, the patient suffers from an x-ray burn which amounts to a severe disfigurement, but this is not the sum-total of her disability. Over the thyroid cartilage, at its most prominent part, there is continuous exfoliation with pronounced cicatricial contraction, "woody" infiltration, and adhesion of the dermis to underlying structures. The contraction prevents full extension of the neck, and is so tender that a collar cannot be worn.

In my opinion the dermatitis here present may subsequently undergo malignant changes, and with the object of forestalling such a catastrophe the patient has agreed to undergo an operation for excision and plastic repair of the adherent parts of the skin.

In summarizing the main issues at stake, I would again assert—

1. That x rays, while selective up to a point, cannot be relied upon in the present state of their physical application to differentiate their action, in the strictly scientific sense, on normal cell structures.

2. It follows, therefore, that they should not be used with the sole object of combating facial hypertrichosis. I would go farther, and maintain that their employment in such cases is unjustifiable, and a direct contravention of the accepted adage, "*primum non nocere*."

3. The latent period in the evolution of x-ray stigmata, after the cure of the primary indications for their use, is a complex and indeterminable coefficient, in which the penetration power of the rays employed and the eutaneous idiosyncrasy of the individual patient are factors of primo importance.

It would seem, therefore, that where destructive doses have been employed the operator can never guarantee his patient against the ultimate appearance (at an uncertain date) of one or more of the stigmata illustrated by my unfortunate patient. It is only in cases of malignant disease that destructive as opposed to inhibitory radiotherapy (as for acne, keloid, oily seborrhoea, etc.) is justifiable.—I am, etc.,

London, W., Oct. 27th.

HENRY C. SEMON.

TREATMENT OF LEPROSY.

SIR,—Many articles and reviews of books and papers have appeared in medical journals on the treatment of leprosy by injections of soaps of the fatty acids of chaulmoogra oil, or the esters of this oil. This treatment has been lauded as though it will effect a cure for the majority of patients. There have been many "cures" for leprosy, and each has received great praise. Perhaps the present cure has received more attention than any other, yet many of us have not forgotten how nasty and benzoyl chloride were extolled about sixteen years ago. I know a number of medical men who have persevered with the treatment by gynocardates in leprosy, and have not had good results.

This treatment has been tested extensively in Ceylon, but with disappointing results. Dr. Muir's preparation, named "eeco," was tried for many months on a large number of patients in the leper asylum; the medical superintendent and his assistants kept very careful records and charted the distribution of the skin lesions and the changes in the sensations of each patient every month. But after many months the results were so disappointing that no pronouncement could be made as to whether the treatment was of any value or not. I think that three points have received too little attention:

1. That most who become infected with leprosy undergo a natural recovery, and that the earliest stages of the disease are very common in the inhabitants of countries where leprosy is rampant. If a number of the lower classes of such a country as Ceylon are examined it will be found that many of them show such early signs of past leprosy, as: (a) patches of anaesthesia; (b) wasting of the thenar and hypothenar eminences; (c) loss of toes; (d) slight thickening of the ulnar nerves. Most of these patients have recovered from the infection, but not from all the results of it.

2. That most of the lepers, who are segregated, are in the later stages of the disease.

3. That the disease in its attack upon a patient waxes and wanes, and that natural cures are far more common than is usually believed.

In some respects leprosy is comparable with tuberculosis, in which disease so many recover from the early stages. The praise that this treatment has received has raised the hopes of thousands of lepers, who I believe are doomed to bitter disappointment.—I am, etc.,

LUCIUS NICHOLLS, M.D., Cantab.,

Director of Bacteriological Institute, Ceylon.

Falloon, Cambridge, Oct. 28th.

VACCINE TREATMENT OF CHRONIC BRONCHITIS.

SIR,—I have read Dr. Mackey's paper (October 21st, p. 715) on this subject with interest, as I have been treating cases of this kind in this way since 1909. Initial enthusiasm is apt to be damped down from time to time, but if it has a substantial basis to rest upon it ultimately burns less brightly, perhaps, but with a steadier light. In spite of failures I can in the main confirm Dr. Mackey's estimate of the utility of this treatment. If I were now compelled to treat these patients with stock expectorant mixtures only, I should feel pretty much like a pugilist whose right hand was tied behind his back. I think the real point of interest to-day, in connexion with chronic or recurring catarrhs of the respiratory tract, is not whether vaccine therapy is useful in the majority of cases, but why it fails in a minority. I wish to direct attention to some causes of failure.

During the war I prepared autogenous vaccines for some 30 to 40 cases of chronic bronchitis in soldiers. There was no appreciable improvement in any of them. They had all been "gassed." I should be interested to learn whether others have been more successful. Where one has to deal with advanced emphysema, bronchiectasis, nephritis, or very high blood pressure it is too much to expect results which will satisfy everyone. It is true that some of these cases may be improved and occasionally I have seen a surprisingly good result; but they are difficult and uncertain. For example, I treated a patient in the Manchester Northern Hospital (Dr. Sturrock's case). There was extremely fetid expectoration and a high temperature which had persisted for many weeks. After the first inoculation there was immediate and striking improvement. The child was sent to a convalescent home in a few weeks almost well. On the other hand, I treated a similar case in Accoats Hospital (Dr. Melland's case), with the result that the patient left the hospital after the first inoculation. The reaction was so severe that the cure seemed to him worse than the disease! This experience emphasized the necessity for minimal initial doses.

But even in uncomplicated cases of chronic catarrh one fails occasionally to do any appreciable good. Dr. Mackey's paper may supply the explanation in some cases, but may I suggest another? It is well known in large pathological laboratories that when a series of rabbits, for example, is inoculated periodically for some weeks with sheep's red blood cells, a very potent antiserum is developed in the great majority of the animals. But its potency is by no means constant, and exceptionally it may be found impossible to obtain a useful antiserum from an individual rabbit whose tissues fail to respond in an average manner. This is a fundamental difficulty in immunization which, I fear, accounts for some of our failures in apparently suitable cases of the kind under consideration.

There is another group of cases to which I wish specially to direct attention. I have treated a number of patients in this way who were said by more or less competent judges to be suffering from laryngeal or pulmonary tuberculosis. I failed, however, to find tubercle bacilli in their sputa. Some of the results were extremely gratifying. In these, I think, the diagnosis was probably incorrect. But I may recall the fact that some tuberculous patients have a history of susceptibility to recurring catarrhs prior to the development of recognizable tuberculosis and one may assume that in many of these patients closed tuberculous lesions existed when only evidence

of catarrh was present. Cure of the catarrh, by relieving them from cough—that is to say, from violent respiratory movements—favours the spontaneous cure of incipient tuberculosis. I suggest that doubtful cases of the kind should be treated in this way before being finally classified as tuberculous. If the treatment fails to do good, at all events the main cause of the failure is here made evident by subsequent developments.

Finally, failure of vaccine treatment may be due to various forms of nasal obstruction or chronic infection of one or more of the accessory sinuses. Appropriate surgical treatment is here an essential preliminary to successful vaccine treatment. I do not suppose that these causes of failure exhaust the list; they are merely those which I myself have encountered in practice.

With regard to Dr. Mackey's modification of the ordinary technique, it appears to me on *a priori* grounds to be sound. I shall certainly try it.—I am, etc.,

Manchester, Oct. 27th.

J. STAVELY DICK.

THE RELATION OF ALOPECIA AREATA AND SQUINT.

SIR,—The cases of association of alopecia areata with strabismus recorded by Dr. Goodwin Tomkinson (September 16th, p. 505) and commented upon by Dr. Harford (September 30th, p. 616) tend to confirm the opinion I have formed of the cause of squint, after investigation of nearly 1,000 cases of heterophoria and squint in the past two years.

Last February I was consulted by a woman of 32 who complained of pain at the back of the eyes and swelling of the lids, the symptoms being worse when she was sewing or reading. She had in the right eye, 0.5 D. myopic 5° latent divergence. The eyes both ovaries had been removed for cystic disease in July, 1921. She had had transient attacks of baldness since the age of 10. She could remember no emotional disturbance at that time. After the ovarian operation the hair came out "in handfuls." The eyebrows and eyelashes have fallen since the age of 25. They grow again, but are grey. Since the operation they have not grown again on the left side. She now has several large areas of baldness. She has a fibrillary twitching of the orbicularis muscles, affecting each side alternately. Afterwards she remembered that she had had a shock when she was 10 years old. Her letter is worth quoting, since it contains several items of psychological significance:

"I was staying in a little village with some friends. There was a man living in a hut on the downs near by who was very strange in his manner. Sometimes he wriggled about as he walked through the streets and along the downs. The villagers said that some years before my visit he had been treated to bovery snakes were

little later in the evening someone whispered to me that he was Old Dan's brother. I was so frightened that I rushed out of the room to my mother, and was led to go home at once. It was only a joke; the man was not related to him at all, but I was terribly frightened, and it took a long time for them to persuade me to stay there a week or two longer. It all seems very foolish now, but at the time I was terrified. I always had a great horror of anything or anybody that was not quite normal. This is all I can remember of the fight I had when 10 years old."

Dr. Harford has referred to my conclusion that squint is intimately related to left-handedness and stammering, either in the person or the family. The case under consideration exemplifies this. She is left-handed in a noticeable but not uncommon manner. The left hand is used for cutting out material and for cutting bread, but she holds the knife in the right hand when using knife and fork. A spoon is held in the left hand, and she is also left-handed for threading needles, but not for sewing. She would feed chickens with the left hand, but would knock a door or ring a bell with the right. The patient's mother is left-handed. Two brothers are living, one of whom stammered when a small boy. She thus suffers from latent squint and alopecia (and loss of eyebrows and eyelashes), is left-handed, and has a family history of left-handedness and stammering. It would be interesting to know if Dr. Tomkinson's cases had a similar family history.

The following history of another family with similar associations was kindly sent to me by a fellow worker:

The father's hair went perfectly white at the age of 21. He was feared or disliked by all his children. He took to drink after the death of his wife, who died of consumption at the age of about 50. The eldest daughter died of consumption at the age of 20. The second daughter squinted. She was described as of morose disposition, which she said was in order to be different from her father. The next child, a son, was morbidly shy; he was killed in the war. The youngest daughter was left-handed. She had alopecia areata from 10 to 12 years of age.

Dr. Rivors,¹ tuberculosis officer of the Barnsley district, has drawn attention to the fact that left-handedness and squint are related to the incidence of pulmonary tuberculosis. In the above case it will be noticed that two members of the family died of consumption.

I propose to deal with the significance of these phenomena on another occasion, but I may state that I am firmly convinced of the hysterical nature of concomitant squint, and this is illustrated by a case which answers Dr. Harford's question as to the possibility of curing squint by psychological methods.

A girl of 7 was brought to me at the school clinic by her sister aged 11. The younger child, who had a convergent squint, was cowed and shrinking; the older was more self-possessed, and was able to give a vivid account of the situation at home. The father, a bully, showed his irritation at his child's squint by beating her, which made the squint worse. I took the child upon my knee, petted and comforted her, won her confidence, and in a few minutes the squint of about 25° had disappeared. Nor could it be induced again before we parted, although I conjured up a picture of the unhappy home to which she had to return.

When she attended the clinic a few weeks later I failed to recognize her amongst other children. It seemed to me that she resented this, and the former friendly relations could not be re-established. She sulked and squinted the whole time. She was offered a penny, but refused to take it. The penny was then put on a table near the door, so that she might take it as she left, if she changed her mind. An hour later I noticed that she had gone and left the penny on the table. This rejection was striking, inasmuch as she was obviously very poor. At the third visit she still squinted. I talked to her as to an adult, expressing my disappointment, and frankly apologized for any shortcomings in my treatment of her, at the same time saying I was quite ignorant as to the nature of my offence. At last she melted, gave a little smile—the only friendly sign since her first visit—blinked her eyes, and the squint had gone. I was delighted, and asked her to accept some pennies as a reward. This gave great offence. She sulked, refused to have anything more to do with me, and though she was again given a chance of taking the pennies unobserved by me, she left the room with a squint and without the pennies. She has not returned to the clinic since that time.

This sort of experience has been repeated on several occasions. I have had recently several children who will squint or recover parallelism on request, and only within the last month I have had a boy of 14 who has been wearing glasses for squint for years, and found them indispensable, and who yet was able to maintain binocular vision without them as soon as his relations with his parents had been readjusted.—I am, etc.,

Southsea, Oct. 20th.

W. INMAN.

LUMINAL IN MIGRAINE.

SIR,—The article on luminal in migraine (BRITISH MEDICAL JOURNAL, October 28th, p. 786) by Dr. Wilfred Harris leads me to say that I have had equally good results from the use of this remedy. I first prescribed it in May, 1922, quite empirically on the assumption that as its exhibition had been so successful in epilepsy it might at least do some good in migraine—a paroxysmal neurosis almost as prostrating and disabling as epilepsy itself. I have only so far had occasion to try it on four patients, all men, but the results have certainly exceeded my expectation.

Space prevents my going into the cases in detail, but, with the exception that in only one case was there an aura, the symptoms in each patient were typical of migraine, the homiocrania advancing after a few hours to vomiting and for the time being causing utter prostration. In one patient the attacks occurred roughly every ten days, and in the other three the intervening period varied between three and five weeks.

I saw the first patient in May and the others in June. All were ordered the same dose—namely, half a grain of luminal three times daily—and they have continued taking this amount ever since. The patient, who was accustomed to his bout of migraine every ten days, has only had one attack since—namely, on August 4th—and this was not followed by vomiting, whereas all previous attacks invariably were. The other three patients have up to the present been completely relieved.

In each case errors of refraction had previously been excluded. One of the patients contracted gonorrhoea four years ago, and he had his first attack of migraine two months later. It is only fair to say that while he has been under the influence of luminal he has also been treated for prostatitis, and it is of course theoretically possible—though

¹ Lancet, February 12th, 1921.

improbable—that the removal of this toxic focus has contributed towards his relief.—I am, etc.,
 London, W., Oct. 30th. REGINALD HEARN, M.D.

PSYCHO-ANALYSIS.

SIR,—Dr. McBride asks two questions in his last letter, and if I do not make some sort of reply I may be accused of running away.

The first asks how the intolligent student is “to reconcile the theory of the unconscious with known physiology.” This same wonderful fellow, according to Dr. McBride, visualizes ideas as nerve cells and so on. No one will object to the vision if it does him or anyone else any good, but as he has no facts to support this figment of his imagination he is theorizing in a demoralizing manner. The whole question has been so well discussed by Dr. Hart in his little book that I need not continue further.

The second question assumes for the nth time that psychoanalysts suggest ideas to their patients. The only reply required is a direct negative.

After all, it is easy to be destructive and to ask questions. I could put a few to Dr. McBride. I shall not, however, ask him his views as to the nature of dreams. He might reply with a list of literature which would be almost endless. Freud has summarized it in the first chapter of his book, and how futile it all is! Nor shall I ask him the nature of hysteria, for the above reason also. But I would very much like to know the opinions of himself and his friends regarding obsessions and phobias—their origin, theoretical explanation, and treatment.

I shall be pleased to read any books I may be referred to on the subject, with one exception only—that the word “unconscious” is not to be mentioned therein.—I am, etc.,

City of London Mental Hospital,
 near Dartford, Kent, Oct. 29th.

R. H. STEEN.

REGISTRATION OF DENTISTS.

SIR,—I shall be obliged if you will allow me to call attention to the following points:

1. On November 1st notices were issued to dentists registered on or after July 28th, 1921, reminding them that a fee of £5 is payable if they desire their names to be retained on the *Dentists Register* for 1923. If there are any of these persons who have not received a notice in course of post they should communicate with this office without delay.

2. All applications for dental registration under Section 3 of the Dentists Act, 1921, must be made within the interim period. The interim period will come to an end on November 30th, and any persons who desire to make application and have not yet done so should write without delay.

3. The *Dentists Register* for 1923 will be published at 10s. 6d., or post free 12s. Copies, however, which are ordered and paid for prior to January 1st, 1923, will be supplied at 7s. 6d., or post free 8s. 6d.—I am, etc.,

Dental Board of the United Kingdom,
 44, Hallam Street, London, W.1, Oct. 19th.

NORMAN C. KING,
 Registrar.

Universities and Colleges.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN ordinary quarterly Comitia of the Royal College of Physicians of London was held on Thursday, October 26th, at 5 p.m., the chair being taken by the President, Sir Humphry Rolleston.

The following candidates were admitted as Members:

Mahomed Khalil Abdel-Khalik, L.R.C.P., Alexander Gordon Biggiani, O.B.E., M.B.Edin., Richard Hill Coombs, M.D. Buck., F.R.C.S., Stuart Jasper C. wa te, M.B.Lond., George Norman Ier, M.D. Edin., 9 Blunford, M.B. Manch., Robert Cecil Priest, M.B. Camb., L.R.C.P., James Mac ure Smellie, M.D. Edin., William Stobie, O.B.E., M.D. Edin., Donald Woods Winnicott, L.R.C.P., Lewis Ralph Yealand, M.D. Ontario.

Licences to practise physic were granted to the following 127 candidates who had conformed to the by-laws and regulations and had passed the required examinations:

M. A. Afia, J. H. André, P. B. Atkinson, Hawah K. N. Attacoullah, J. R. Azu dia, R. A. de C. Basto, W. Beaumont, A. O. Bekenn, F. J. Biddle, H. Poger, E. B. Krooke, A. W. Brown, Margaret M. Brownstone, A. G. Bull, Gertrude B. G. Carden, C. O. Carson, N. E. D. Cartledge, S. A. R. Chadwick, Grace D. Chambers, E. F. Chapman, J. L. Chaudhuri, J. Cohen, M. J. Cohen, F. M. Collins, J. L. Cox, Eleanor M. Creak, A. L. Crockett, H. P. Dalry, D. Davidson, D. A. Davies, F. Davies, Kathleen F. Davies, G. Denton, and M. Dixon, J. H. Doggart, Alice E. Dove, Winifred Ealand, A. M. Edwards, C. Fenwick, L. French, Lydia S. Fuller-

Maitland, I. W. Gallant, C. P. R. Gibson, W. Girdle, S. Glass, Janet V. Good, J. Griffiths, A. W. Hall, H. A. H. Harris, H. W. Harvey, J. K. Hasner, E. Haworth, Evelyn N. Heather, F. J. Hector, H. S. Inger, W. G. R. Hore, W. E. Howell, P. Hudson, K. E. A. Hughes, D. M. Hutchinson, M. B. Jay, A. D. W. Jones, E. P. Joshi, C. L. Kark, R. W. C. Kelly, F. L. Lach, Gladys M. Lambourne, H. D. Dawson, Catherine E. L. Lendrum, E. G. Lowie, E. Lister, J. L. Livingston, A. E. Lorenzen, F. Louis, G. S. Lund, Mary C. Lynch, Elizabeth K. Mackay, Elizabeth McKerraw, Elizabeth Maitland-Jones, R. Mannars, A. W. Harrison, V. M. Matthews, H. C. Maudrel, E. B. Messinger, Mary Michael, A. M. Monnerieff, Herta Moos, J. A. Morton, Lily Moss, K. Olfsson, Dorothy Pantin, I. N. O. Price, A. B. Rao, J. W. Rigby, C. V. D. Rose, J. S. Salt, C. Satyarnai, H. S. Savage, Effeen M. Easton, J. Seelenfreund, I. A. Senanayake, D. G. Sharp, P. H. Sharp, C. Shephard, H. L. Shepherd, D. K. Shuttleworth, A. E. Slater, G. M. Soker, Emma M. Store, A. G. Storey, B. H. Stirling, H. Sumner, H. J. V. Sutton, C. G. Taylor, Agnes W. O. D. Thomas, M. A. Townsend, London Tower, W. J. Vickers, A. H. C. Visick, Doreen G. C. Walker, J. A. Walker, S. F. Wickramasinghe, W. G. Wickremesinghe, Helen P. Wilkinson, D. Williams, Caroline I. Wright.

On the recommendation of the Council, Dr. J. H. Drysdale was appointed an Examiner in Medicine.

Communications were received from the Secretary of the Royal College of Surgeons reporting proceedings of the Council of that College on July 27th and October 12th; from the Secretary of the College of Preceptors, thanking the College for the assistance given by its representatives on the joint committee on the Physical Education of Girls (BRITISH MEDICAL JOURNAL, August 19th, pp. 321 and 316); from the Secretary of the Conjoint Board of Scientific Societies, submitting a scheme for the reconstitution of the Board, asking for observations thereon.

On the motion of the Senior Censor, it was resolved to restore the Licence of the College withdrawn from Thomas Stoney Sharpley in April, 1919.

The Registrar moved, for the second time, that By-law No. CXIV, relating to candidates for the membership, be repealed. The by-law reads as follows:

“No candidate shall be admitted to examination who is engaged in trade, or makes any arrangement with a chemist or any other person for the supply of medicines, or who practises medicine or surgery in partnership, so long as that partnership shall continue.”

This was passed for the second time, and the by-law accordingly is now repealed.

On the nomination of the President, Professor E. H. Starling was appointed to deliver the Harvelan oration, and Dr. John Hay to deliver the Bradshaw lecture.

At the suggestion of the President it was decided to hold a conversatione in the College in November.

The arrangements in regard to the Lloyd Roberts lectureship and the legacy left for this purpose were approved in accord with counsel's opinion.

Reports were received from the Committee of Management recommending the adoption of new regulations for the Preliminary Examination in General Education, and for the Pre-medical Examination in Chemistry and Physics, together with the revised synopses of chemistry and physics, to come into force on January 1st, 1923. The Committee also recommended the adoption of new regulations of professional study for the diplomas of L.R.C.P. and M.R.C.S., together with the synopses of anatomy and physiology and the syllabus of the course of instruction in general biology.

Dr. R. A. Young was appointed a member of the Committee of Management in the place of the late Sir James Galloway.

After some formal college business had been transacted the President dissolved the Comitia.

UNIVERSITY OF OXFORD.

THE Faculty of Medicine has re-elected Sir Frederick Andrewes, D.M., Pembroke College, F.R.S., to be a member of the Board of Electors to the Professorship of Pathology.

An award of the Francis Gotch Memorial Prize will be made in the present term.

The Wide Reader in Mental Philosophy announces that Monsieur Emil Coné will lecture for him on the subject of “Suggestion” in the Examination schools on Saturday, November 25th, at 12 noon.

Radclyffe Prize, 1923.—The conditions for the award of this prize were printed in our issue of October 7th, 1922 (p. 664). Candidates are to submit their memoirs to the Assistant Registrar Building, Broad Street, Oxford, on 1st, 1922. The intended date of the

are to be the Degree Days in the present 2nd; Saturday, November 18th; Thursday, December 16th.

UNIVERSITY OF CAMBRIDGE.

THE total entry of new students at Cambridge is reported to be unprecedented; there are this term 1,589, as compared with 1,491 last year. The matriculation figures for the six largest colleges are as follows: Trinity, 212; St. John's, 131; Gonville and Caius, 118; Christ's, 110; Emmanuel, 109; Pembroke, 106. Jesus and Clare have 86 each, Trinity Hall 73, King's 71, and no college has less than 43 new students. Non-collegiate students number 58. Separate figures for medical students have not been issued.

Draft regulations for the admission of women to the titles of degrees, in accordance with last year's decision, have been prepared and presented to the Senate.

The munificent bequest of the late Mr. A. Marmaduke Shield to the Cambridge Medical School was noted in our last issue at page 832.

At a congregation held on October 27th the following medical degrees were conferred:

M.D.—M. S. Thomson.
M.B., B.Ch.—H. D. Gardiner.
B.Ch.—H. E. Cresswell.

* Admitted by proxy.

VICTORIA UNIVERSITY OF MANCHESTER.

Dr. E. J. SIDEBOTHAM, who recently resigned the post of deputy director of the public health laboratory, has been appointed honorary lecturer in public health.

Dr. G. J. Langley has been appointed honorary assistant lecturer in experimental physiology.

The Leech Fellowship has been awarded to C. D. Hough, M.B., Ch.B., and the entrance scholarships in medicine to Florence V. Stephen and N. S. Walls.

UNIVERSITY OF LONDON.

Mr. H. J. Waring, M.S., F.R.C.S., has been elected Dean of the Faculty of Medicine for the period 1922-24.

Lectures on Secretions and Internal Secretions.—A course of eight lectures on "Secretion and Internal Secretion" will be given by Professor Swale Vincent, M.D., D.Sc., Professor of Physiology in the University, at Middlesex Hospital Medical School, Union Street, at 5 p.m., on Mondays and Thursdays, November 6th, 9th, 13th, 16th, 20th, 23rd, 27th, and 30th. Attendance at this course is recognized in connexion with the B.Sc. (Honours) Degree in Physiology. Admission is free without ticket.

UNIVERSITY OF LEEDS.

The University Council has appointed Miss E. M. Hickman, M.B., Ch.B., to be Demonstrator in the Department of Pathology and Bacteriology, and Mr. R. B. Tasker Honorary Demonstrator in Anatomy for dental students.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

NOTICE has been given on behalf of the Society of Members of the Royal College of Surgeons of England that the following motions will be submitted at the annual meeting of Fellows and Members which, as already announced, will be held at the College, Lincoln's Inn Fields, on Thursday, November 16th, at 3 p.m.:

1. That this thirty-fifth annual meeting of Fellows and Members again affirm the desirability of admitting as Members to direct representation on the Council of the College, which (as now constituted) only represents those Members who hold the Fellowship; and that it does so in order that the constitution of the Council of the Royal College of Surgeons of England shall be in keeping with modern ideas of true representation; further, that as the Royal College of Surgeons is composed of about 18,000 persons, of whom over 16,000 are engaged in general practice, its annual meeting requests the President and Council to nominate at least two Members in general practice to represent the interests of general practitioners on the Council of the College.
2. That this meeting of Fellows and Members requests the President of the College to make a detailed statement here and now as to all the reasons, legal and otherwise, for the Council's refusal to allow representation on the Council of the Members in general practice; and to state whether legal advice has been taken as to any possible means of overcoming any difficulties in the way of carrying out our wishes; and, if so, to declare what that advice was.

The Services.

NAVAL MEDICAL MEMORIALS.

The memorial at the Royal Naval Hospital, Chatham, will be unveiled at 3.30 p.m. on November 11th by Surgeon Vice-Admiral Sir Robert Hill, Medical Director-General R.N., and dedicated by Archdeacon C. W. C. Ingles, D.D., Chaplain of the Fleet.

Owing to changes in the dresses of many temporary medical officers, reserve nursing sisters, and others who subscribed to the fund, it has not been possible to send separate invitations to all. It is hoped that this intimation will be accepted by them, as well as by all friends and relatives of the fallen, as an invitation to attend the ceremony.

ROYAL NAVAL MEDICAL SERVICE.

FLEET SURGEON JOSEPH H. WHelan, R.N.(ret.), has been awarded the Greenwich Hospital pension of £0 a year in the vacancy created by the death of Fleet Surgeon Peter W. Rolston, R.N.(ret.), on June 13th.

A reunion of the officers of No. 33 General Hospital, B.E.F., is being arranged. It will take place in London on Friday, December 8th, 1922. Those who intend to be present should notify Dr. J. B. McDougall, if they have not already done so in response to the intimations sent out on October 10th.

DR. LOUIS RENON, professor of medical pathology in the Paris Faculty of Medicine, and a well-known writer on tuberculosis, has recently died.

Obituary.

ALEXANDER CRUM BROWN, M.D. EDIN., D.Sc. LOND., F.R. F.R.S.E., F.R.C.P.E., LL.D. ABERD., GLASG., EDIN., ST. AND., Emeritus Professor of Chemistry in the University of Edinburgh.

To the recent graduate of Edinburgh University and to the present-day student there Crum Brown has been simply *nano*—a name with magnificent memories attached, but still little more than a *nano*. It was far otherwise with the graduates and students of the last three decades of the nineteenth century and the first few years of this century to them he was the kindly and extraordinarily learned professor of chemistry whose versatility was a proverb; he was to many of them their first teacher in the University; after years they loved to recall the exciting incidents—the explosions and the malodorous emanations—of his elucidation in friendly fashion to try to imitate his method (of his own) of lecturing; for a few obstreperous spirits who came into collision with the University authorities his was the voice which pled for leniency and suggested the extenuating circumstance. His retirement from the Chair in 1903 brought an end to those things; he did not indeed cease to play a part in medical affairs—he was, for instance, president of the Edinburgh Medical Missionary Society for five years from 1911 to 1916—but his intimate relations with student life on a large scale ceased. For several years he has been practically confined to his house where, however, he was always ready to welcome old friends and talk with all his old vivacity of all sorts of matters. He became seriously ill only some three weeks ago, and the end of a notable life was reached on October 28th.

Alexander Crum Brown was born on March 26th, 1835, twenty-eight years later than his step-brother, John Brown M.D., the author of the inimitable *Rab and His Friends* and *Horae Subsecivae*. His father was the Rev. Dr. John Brown, biblical scholar and minister of Broughton Place Unitarian Presbyterian Church in Edinburgh; his mother (Dr. Brown's second wife) was the daughter of Alexander Crum of Thorburn, near Glasgow. He received his education at the Edinburgh Royal High School, at Millhill School, at Edinburgh University (M.A. 1858, M.D. 1861), in London (D.Sc. 1865) and in Germany under Bunsen and Kolbe. In 1863 he began to lecture on chemistry in the Edinburgh Extramural School, and, not having too many students, he was able to give much time to original research in pure and applied chemistry. In 1869 the election of Professor Lyon Playfair as M.P. for Edinburgh at St. Andrews Universities gave the young lecturer his chance and he was appointed to the vacant Chair of Chemistry in the University. There he worked for nearly forty years and became famous for many other things besides chemistry. He had already in 1868, along with Dr. (afterwards Sir) Thomas R. Fraser, been awarded the Macdougall Brisbane Medal of the Royal Society of Edinburgh for an investigation on the connexion between the chemical constitution and the physiological action of salts of ammonium (alkaloid) bases. In 1875 he was awarded the Keith Prize for the research which proved that the semicircular canals of the ear were the origin of the sense of rotation. His M.D. thesis (1865) unfortunately not published till 1878, was on the theory of chemical combinations, and contained much original thought rather remarkable as the work of a medical student, summarized by Dr. Leonard Dobbin in *Edinburgh's Place in Scientific Progress* (p. 53, 1921). Professor Crum Brown's original work in chemistry was specially centred in graphical formulae, in the theory of benzene substitution, in the problems of stereo-isomerism, in the electrolytic synthesis of dibasic organic acids, and in the relation of chemical constitution to physiological action (to which reference has been made). He was closely connected with the Royal Society of Edinburgh, and acted as secretary for some years. As he has been already shown, Professor Crum Brown did not confine himself to chemistry. To quote the author of *Quasi Curser* (1883):

"His knowledge of mathematics, of philology, of modern languages, even such as Russian and Chinese, and of church history, is known to his friends, while under the stores of 'general information' there exists an acute 'general' intellectual power that takes kindly, as any Schoolman, to the labyrinthine and paradoxical; perhaps he believes more than most of us in a region where paradoxes are not only soluble but solved."

This tribute paid to the professor comparatively early in his long life was justified more and more as the years went

by, and stories were current that at dinner parties he discussed matters ranging from Presbyterian paraphrases to Chinese music, and that he once began a series of lectures on the alphabet, but at or several meetings had to stop as he had got no farther than A. How massive was his learning and how widely recognized might be inferred from the numerous honorary degrees which he received, and how greatly beloved he was by his students may be guessed from the fact that to them he was and will ever remain, not "Professor Brown" but "Crummie."

He married Miss Jane Bailie, daughter of the Rev. James Porter, Drumlee, co. Down; she died in 1910. One of the best known photographs of Crum Brown is that which shows him (in 1877) as the centre figure in a once famous club called the "Round Table," with Argyll Robertson, Sir Thomas Fraser, Joseph Bell, and many other Edinburgh notabilities grouped around him. He was very truly the centre for many years of much of the best thought in his Alma Mater, and he had a well-deserved reputation for kindness of heart and sheer goodness which rested upon the surest foundations. It was not for nothing that there ran in his veins the blood of Brown of Broughton Place and that older Brown of Haddington, the author of the *Self-interpreting Bible*.

GEORGE RENDLE, M.R.C.S., L.S.A.,

Late Secretary of the Medical School of St. Thomas's Hospital.

THE death of George Rendle in October has removed one who in a kind and unassuming manner exerted an influence on the careers of many generations of St. Thomas's men. He was born in 1843, the son of Dr. William Rendle, the historian of Southwark and incidentally of St. Thomas's Hospital. He was educated at Merchant Taylors School, and later at the medical school of Guy's Hospital, from whence, in 1865, he became a Member of the College of Surgeons and a Licentiate of the Society of Apothecaries.

Four years of private practice in conjunction with his father, however, led him to conclude that he had not found his *metier*, possibly a determination due to his extreme conscientiousness of disposition. He then entered the Civil Service and as a "writer" in the General Register Office he received special commendation. In 1883 he became secretary to the medical school of St. Thomas's Hospital, a post which he held until 1905, and then, as a result of failing health, he relinquished the more responsible duty for the less exacting one of librarian during a further period of eleven years.

Rendle was an actual product of the old "United Hospitals." Entering on his professional life at a time when the two hospitals faced each other in St. Thomas's Street, he witnessed the disappearance of the parent institution and the resurrection at a higher spot on the banks of the Thames of the new St. Thomas's which was destined to absorb his future energies and at which he passed the main portion of his life.

Few men can have entered more devotedly on their duties; he lived for the school, and was its secretary during the years when it was steadily increasing in size, and in point of numbers reached its zenith. He was actively associated with the various structural extensions and improvements necessitated by this unexpected growth of the classes. On him also fell the responsibility of familiarizing a succession of deans with the duties they had undertaken, of maintaining continuity in the policy and administration of the school, and in the evolution of changes called for by the medical curriculum. The acquired of every detail of the education, and the special requirements of the various universities and licensing bodies rendered him an invaluable colleague, and in consequence it was rare that the dean could fall into error in matters either of advice or action. No less valuable was his association with the younger members of the school; his ripe experience was at the disposal of all who came to him, and he made their interests his own. Loyalty, transparent honesty, and discretion, marked all his actions; punctilious in the fulfilment of every duty and methodical to a degree in the arrangement of his work, he gave of his best freely, while he was kindly and considerate to all. No ungenerous word or careless gossip ever escaped him in his office, the daily meeting place of the staff for so many years, and no one had ever occasion to repent having reposed a confidence in him. His neat carefully dressed figure was for more than thirty years one of the most familiar objects of St. Thomas's, and was greatly missed by his friends when he retired. His love for the institution, which he served so

long and faithfully, cannot be better illustrated than by the sentence which accompanied the announcement of his death in the *Times*, which asked anyone desiring to send flowers to his grave rather to make a contribution to the Samaritan Fund of the hospital.

LACHLAN G. FRASER, M.D.,

North Shields.

WE regret to record the death on October 5th, after a long and painful illness, of Dr. Lachlan George Fraser, who was one of the best known and most highly respected medical men in the north-east of England. Dr. Fraser received his medical education at the College of Medicine, Newcastle-upon-Tyne, and graduated M.B. (honours) and B.S. in 1895, M.D. in 1903, and M.S. in 1904 at Durham University. He joined his uncle, Dr. F. C. Mears, in partnership at Northumberland Square, North Shields, and succeeded to the practice on the death of Dr. Mears two years ago. He held the appointment of honorary surgeon to the Tynemouth Infirmary, an institution to which he devoted a great deal of his time; he had taken an active part in its administrative affairs practically from its foundation. He was the author of many contributions to medical literature, mainly in this Journal, and he was the author of a prize essay on talipes equino-varus in 1903. He took much interest in all kinds of sports and athletics, especially in swimming, and was honorary surgeon to the Tynemouth Amateur Swimming Club.

Dr. Lachlan Fraser had long taken an active interest in the work of the British Medical Association, and filled with distinction every office in the North of England Branch, including that of president. He was secretary of the Tyneside Division of the Association from 1902 to 1913, a period which covers the years of strenuous work during which the National Insurance Bill was under discussion. Dr. Fraser, notwithstanding the calls of a busy practice, did splendid work for the Association during those years and earned the gratitude of his fellow practitioners for his labours. He was elected chairman of the Tyneside Division of the Association in November, 1917, and still held that position at the time of his death. He was for several years a member of the Tynemouth Insurance Committee, and he was elected president of the Northumberland and Durham Medical Society, but never filled the chair, for the first meeting of the session at which he should have presided was on the day of his death. He was one of the very best type of general practitioner, and his loss will be severely felt in an area much wider than his own district. The funeral was most impressive; it was attended by medical men from the whole countryside.

MR. HUGH WHITWELL of Norwich, who died on October 20th at the age of 46, came of an old Yorkshire family. He was educated at Uppingham and Cambridge University, and received his medical training at St. Bartholomew's Hospital. He took the diplomas of M.R.C.S. and L.R.C.P. Lond. in 1901, and subsequently served as house-physician at Bartholomew's Hospital, senior house-surgeon at the Royal Free Hospital, and assistant medical officer to H.M. Prison, Norwich. About eighteen years ago he entered into partnership with Mr. H. S. Robinson and Mr. H. C. Nance in Norwich, and on their retirement he became senior partner, with Dr. B. B. Riviero as his colleague. Some years ago he was appointed to the staff of the Jenny Lind Children's Hospital, to which he was senior surgeon at the time of his death. He served for two and a half years in France during the war, first as medical officer with the Yorkshire Hussars, and afterwards as a surgical specialist at a general hospital. His health gave way under the strain of war service, and he was invalided out of the army in 1918. Before going to France he did valuable work at the Lakenham Military Hospital and as temporary assistant surgeon at the Norfolk and Norwich Hospital. He was a good golfer, and before going to Norwich had played cricket for the Yorkshire Gentlemen. He was also a keen supporter of the Norwich staghounds. He underwent a serious operation on October 16th, and after making substantial progress for two days unforeseen complications arose which caused his death.

DR. THOMAS CARLETON RAILTON, who died at Buxton on October 4th at the age of 78, was educated at the Royal School of Medicine, Manchester, and St. Bartholomew's Hospital. He took the diploma of M.R.C.S. Eng. in 1869, and

proceeded to the F.R.C.S. in 1872; he graduated M.B.Lond. in 1873 and M.D. in 1882, and in the latter year he also graduated B.Sc.Viet.; in 1888 he took the diploma of M.R.C.P.Lond. Dr. Railton was formerly in practice at Manchester, and held appointments on the honorary staff of the Northern Hospital for Women and Children, to which institution he was at the time of his death a consulting physician. He retired from medical practice some years ago and went to live in Buxton. He was the author of many contributions to current medical literature and of several works on diseases of children.

The death took place suddenly on October 19th of Dr. JOHN GEORGE WALLACE-JAMES, of Tynno House, Haddington, eldest son of the late Dr. Robert Wallace-James, H.E.I.C.S. Dr. Wallace-James received his medical education at the University and Royal College of Surgeons of Edinburgh. He had been in practice for some years at Haddington, and was held in high regard in the district. The funeral, which took place on October 23rd, was attended by the Provost, magistrates, town council, and by other public bodies in Haddington.

Medical News.

At the annual dinner of the London School of Tropical Medicine on Wednesday, Sir Arthur Robinson, of the Ministry of Health, said that a scheme was under consideration whereby the London School of Tropical Medicine would be incorporated with the new Institute of Hygiene, founded with the assistance of the generous gift made by the Rockefeller Fund. The amalgamation, however, must be on such a basis as to secure the continuance of the great work done by the school. Sir Havelock Charles said that if the aspirations of the school were met the adhesion of the staff and students to the new arrangement would be freely given.

LECTURES on tropical hygiene in its relation to the public health service will be given at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., at 4 p.m., on November 20th, 21st, 22nd, 23rd, and 24th, by Dr. Andrew Balfour, Lieut.-Colonel W. W. Clemesha, Professor R. T. Leiper, Lieut.-Colonel H. J. Walton, and Dr. H. B. G. Nowham. The lectures will be illustrated by lantern slides and films; they are primarily intended for sanitary inspectors.

The annual dinner of past and present men students of Leeds Medical School will be held at the Queen's Hotel on Friday, November 17th, at 7 p.m., when Dr. Watson will be in the chair. This is the thirty-ninth annual dinner, and the continued support of past students is asked for. Tickets, 10s. each, exclusive of wine, may be obtained from the honorary secretaries, Mr. J. Shutt and Mr. G. F. Walker, Medical School, Leeds. Guests may be invited, who need not be members of the medical profession.

The twenty-seventh Congress of the Italian Society of Internal Medicine was held at Florence from October 21st to 24th, when the following subjects were discussed: duodenal ulcer, introduced by Professor Ascoli; jaundice, introduced by Professors Caporali and Zoia.

A CONGRESS of French-speaking dermatologists will be held at Strasbourg from July 25th to 27th, 1923, on the occasion of the centenary of Pasteur. Further information may be obtained from Professor Pautrier, 2, quai Saint-Nicolas, Strasbourg.

The Wellcome Museum of Tropical Medicine and Hygiene, Wellcome Bureau of Scientific Research, 26, Endsleigh Gardens, N.W.1 (near Euston Station), gives a graphic presentation of tropical medicine and hygiene, and is open during the week to all medical men from 9.30 a.m. to 5.30 p.m. (Saturdays 9.30 a.m. to noon). On Wednesdays at 2 p.m. visitors will be shown round the museum by the curator.

The *London Gazette* announces that Dr. Hyman Finklestone Sayliss, formerly known as Hyman Finklestone, has by deed poll assumed the surname of Sayliss in addition to that of Finklestone.

The King Edward VII Hospital Fund has made a further distribution of £100,000 out of the proceeds of the Hospitals of London Combined Appeal, making, with £150,000 distributed on August 3rd, a total to date of £250,000. The hospitals are being informed that, in accordance with the original scheme of the appeal, the grants are based, *inter alia*, on the number of occupied beds and out-patient attendances, and on the evidence as to their general efficiency, financial needs, and the efforts made to assist the appeal; but that neither the first

payment on account, nor the first and second taken together, will necessarily represent the judgment of the King Edward Fund as to the proportions in which the ultimate total proceeds of the appeal should be allocated.

A DANCE in aid of the Westminster Hospital Students' Union will be held at Princes' Galleries on Friday, November 24th, at 9 p.m.

The dinner of the past and present students of the Royal Dental Hospital of London will be held at the Trocadero Restaurant on Saturday, November 25th, at 6.30 for 7.0 p.m., when Mr. P. L. Webster will preside.

The annual dinner of the medical staff of the Central London Throat and Ear Hospital was held at the Trocadero Restaurant, London, on October 26th, with Dr. James Atkinson in the chair. After the loyal toasts had been honoured, the chairman proposed the health of "The Guests" in felicitous terms, and Mr. W. J. C. Nonso and Dr. W. H. Kelton replied. The toast of "Our Hospital" was proposed by Sir Sydney Russell Wells, who made a plea for a better organization of post-graduate education in London by co-operation among the special hospitals. Sir James Dundas-Grant replied, and Mr. Kershaw, secretary to the hospital, contributed some amusing reminiscences. During the course of the evening a presentation of a silver loving cup was made by Dr. A. Wylie, on behalf of the medical staff, to Mr. W. Stuart Low, who recently retired from the active staff of the hospital.

The late Mr. Wilfred Stones, of Wilmslow, Cheshire, who died in July last, leaving net personalty of £55,636, has left the residue of his estate to be divided into ten parts, three for the Manchester Royal Infirmary, two each for St. Mary's Hospital, Manchester, and the Children's Hospital, Manchester, and one part each to the Manchester Eye Hospital and the Northern Counties Hospital for Incurables, Maudeth, and one part between Christ's Hospital Cancer Pavilion and the Manchester and Salford Hospital for Skin Diseases.

The first meeting of the new session of the Röntgen Society will be held at the Institution of Electrical Engineers, Savoy Hill, Victoria Embankment, W.C., on November 7th, at 8.15 p.m., when the presidential address will be delivered by Sir Humphry Rolleston, K.C.B., on acute constitutional symptoms due to radiations.

The annual dinner of the Cambridge Graduates' Club of St. Bartholomew's Hospital will take place on Friday, November 24th, at 7.30 p.m., at Hotel Victoria (King Edward VII Rooms), with Dr. Herbert Williamson in the chair. The honorary secretaries are Dr. H. N. Burroughes and Mr. Reginald M. Vick.

The *London Gazette* announces that the Lord Chancellor has appointed Lieut.-Colonel Nathan Raw, C.M.G., M.D., to be a Medical Visitor of Lunatics so found by inquisition.

The Metropolitan Borough of Holborn has called a conference on rat repression to be held in the council chamber at the municipal offices, 197, High Holborn, W.C.1, on Monday, November 6th. The chair will be taken at 3 p.m. by the Mayor.

In consequence of the Parliamentary election the meeting of the Dental Board of the United Kingdom has been postponed from November 14th to November 21st.

The fourth edition of *Physiology and Biochemistry in Modern Medicine*, by Professor J. J. R. Macleod of Toronto, is in the press and will shortly be issued by Mr. Henry Kimpton. The same publisher is about to publish the tenth edition of Dr. C. E. Simon's *Manual of Clinical Diagnosis by Means of Laboratory Methods*.

A CELEBRATION of the centenary of the birth of Pasteur is to take place in Philadelphia on December 27th, 1922. The provisional programme includes a meeting in the afternoon at the Academy of Medicine and a banquet in the evening, at both of which there will be distinguished speakers.

PROFESSOR LACASSAGNE has bequeathed to the city of Lyons his library, which numbers upwards of 12,000 volumes, and is particularly rich in documents relating to criminal anthropology.

SIR ALMROTH WRIGHT, M.D., F.R.S., will deliver the occasional lecture before the Royal Society of Medicine on Thursday, November 30th, and has chosen "New principles in therapeutic immunization" as the topic. The chair will be taken by the president, Sir William Hale-White, at 5 p.m.

The *Handbook of Leprosy*, by Dr. Ernest Minir, reviewed last week (p. 805), is published in this country by H. K. Lewis and Co. at the price of 10s. 6d.

The late Dr. Matthew Mitchell Bird, formerly medical superintendent of St. Mary's Hospital, Paddington, has bequeathed the residue of his estate, about £10,000, to St. Mary's Hospital for general purposes.

Letters, Notes, and Answers.

owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

Correspondents who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

Persons desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY and BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera*, Westrand, London; telephone, 2633, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus Dublin*); telephone, 4737, Dublin, and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*); telephone, 4361, Central).

QUERIES AND ANSWERS.

INCOME TAX.

G. M." has appealed against his assessment and has been asked by the local inspector to furnish statements based on bookings less bad debts.

"* It is universally agreed that the calculation of a proper allowance for bad debts in the case of a medical practitioner is always speculative and generally unsatisfactory. For this reason it was agreed on behalf of the Board of Inland Revenue some time ago—and also more recently (see our issue of November 19th, 1921)—that unless special circumstances existed objection should not be raised to basing assessments on cash receipts instead of bookings less bad debts. In the long run no difference in the amount of tax paid should occur, but it is dangerous to change from one basis to another. It is agreed that the cash basis is unfair to the revenue in the case of a new practice or a change in proprietorship, but unless there are some special circumstances of that kind "G. M." should press for the acceptance of the normal basis. In any case the "income" on which tax is paid is the earnings in respect of the year of assessment and not for the year when the fees were booked or paid.

J. McC., who left the army service and went into general practice as a partner, cannot average his own previous earnings, but must take his liability as determined by his share of the average profits of the practice. The averaging of past army earnings applies only where the civil earnings are received as employee—as in the case of "J. O'L. M.," referred to in our issue of October 14th, 1922.

F. E. D." bought a 15-h.p. Overland two-seater for £225 in 1916. In 1921 he sold this for £ 00, and bought 11.6 h.p. four-seater Standard for £595. The cost of a two-seater Overland in 1921 would have been £475.

"* The allowance due is £475 - £100 = £375. The inspector of taxes might be reminded that the official witness before the Royal Commission on Income Tax gave evidence to the effect that allowances for cost of replacement would be calculated by reference to the then, and not the original, cost of the plant or machine replaced.

LETTERS, NOTES, ETC.

PSYCHO-ANALYSIS.

R. V. T. CARRUTHERS (Derby) writes: In asking for an anti-Freudian who has seriously studied the subject and given his views in a book, Dr. Steen (October 21st, p. 775) appears to have overlooked Pierre Janet's *Mémoires Psychologiques* (1919), vol. ii, chap. 3.

SWEATING IN PULMONARY TUBERCULOSIS.

R. J. PRIE (Ha bury, Leamington Spa) writes in answer to "Irishman" (October 21st, p. 789): "If he has not done so it is worth while to try the effect of a glass of milk punch before retiring (a glass of cold milk with three or four teaspoonfuls of good old Cognac). A method recommended by Dr. William Porter is worth remembering—namely, note the time of the

beginning of the sweating, wako patient a few minutes before and give him two tablespoonfuls of whisky. It may seem strange to recommend stimulating remedies like milk punch to prevent night sweats, but it must be remembered that in phthisis the tachycardia of the day is generally succeeded by a bradycardia at night. "Irishman" says the hygienic conditions of his patient are superb, therefore it is not necessary to refer to the importance of hygienic bedding, covering, and clothes, and the value of real 'open-air' treatment in preventing sweats. As to medicine, has he tried agaricin gr. 1/20 six hours before sweating is expected, or atropin gr. 1/100?"

DERMATITIS AMONGST CEMENT WORKERS.

In reply to Dr. Dykes's inquiry (October 23rd, p. 826), Dr. James Liddell (London, N.) sends the following extract from *Diseases of the Skin*, by Stelwagon: "Among other trades and workmen a variable dermatitis or cutaneous injury may result: an eczematoid eruption in builders, plasterers, and bricklayers from the plaster, lime, and cement."

THE MILK OF JERSEY COWS.

In opening a discussion on the food value of milk at the National Milk Conference, Dr. Robert Hutchison is reported to have said (BRITISH MEDICAL JOURNAL, October 28th, p. 82.) that he had "found the milk of Jersey cows specially likely to produce bilious trouble on account of its richness." The Honorary Organizing Secretary of the South-Eastern Jersey Club writes to inform us that at a dinner of the Club the suggestion that Jersey milk was deleterious to children was very roughly controverted by several speakers, among them Dr. Harry Corner, who said that he had kept a Jersey herd for twenty-five years, and had never had an infant or child who could not take Jersey milk when properly administered, even after other milk and milk substitutes had failed.

MEDICAL AID FOR RUSSIAN REFUGEES.

Mr. D. ZINOVIEFF (Special Delegate of the Russian Red Cross for Great Britain) and Dr. B. BELLOVSKY, (Medical Adviser to the Russian Red Cross), write: The Russian Red Cross Society (Old Organization) makes an urgent appeal at the present time to all kind friends and sympathisers for help for the destitute Russian refugees. These unfortunate persons, deprived of their own mother country, are scattered all over the world. The above society is doing its utmost to provide at least the minimum of help necessary, but is greatly handicapped by lack of funds. The majority of the Russian refugees are living in Serbia, Bulgaria, and other Balkan States. Though helped to a certain degree by the Governments of these countries, they are in a very distressed condition. One of their chief needs is medical help, for which surgical instruments are very badly lacking. Thousands are suffering and help is urgently needed. The Russian Red Cross, therefore, pleads for assistance by donations in money or in surgical instruments—even old and used ones. Such donations will be most gratefully received at the offices of the society, Chesham House, Chesham Place, London, S.W.1.

MEDICAL GOLFING SOCIETY.

THE autumn meeting of the Medical Golfing Society was held at Littlestone-on-Sea on October 21st, and was a great success. The results were as follows. Singles v. Bogey (cup presented by Mr. Ernest Clarke), won by Mr. H. D. Gillies, 1 up; second, Mr. T. P. Kolesar and Dr. E. Grogono, 2 down. Pairs v. Bogey (cups presented by Mr. G. Dawson and Dr. Roff Greasy), won by Dr. L. W. Bathurst and Mr. E. Laming Evans, 4 down, after a tie with Mr. L. Bromley and Mr. F. D. Sauer, and with Dr. E. Grogono and Dr. L. Welby, at 5 down. Challenge cup for best 18 holes medal round (presented by Mr. E. Canny Ryall), won by Dr. J. Grace, 87 - 9 = 78; second, Sir Milson Rees, 83 - 4 = 79; third, Mr. E. Laming Evans, 89 - 9 = 80. All competitions were played under handicap.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 35, and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 171.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under
Each additional line
Whole single column (three columns to page)
Half single column
Half page
Whole page

An average line contains six words

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning, and should be paid for at the time, should be

the Post Office to receive postal orders or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

330. Influenza.

A. GARVIE (*Glasgow Med. Journ.*, October, 1922, p. 232) combats the conclusion in the report on the "Pandemie of Influenza" issued by the Ministry of Health, that at the first feeling of illness the patient should go to bed at once and remain at rest and in the warmth. He aims rather at preventing the onset of the secondary stage and the spread of infection to other inmates of the house. Observations during an epidemic showed that a definite relationship exists between the household wave and cases developing the secondary stage, and that none of the patients first seen in consultation at the surgery, however serious their symptoms appeared to be, subsequently developed symptoms of the secondary stage, and none died. It was noted that in the primary stage those who did most who suffered most from the flow of nasal secretion and paroxysms of sneezing, and that in a considerable number those were the only symptoms which manifested themselves. Furthermore, in those suffering from the secondary stage, none of the purely primary symptoms were present, and it appeared that the presence or absence of a free flow of nasal secretion had a very intimate bearing upon the subsequent course of the illness. He holds that the chief aim of treatment should be to produce a maximum amount of primary symptoms, especially in those showing a commencing toxæmia, and such an aim is best realized by obtaining a maximum amount of air current in the sick-room associated with plenty of bodily warmth attained by the use of covering and not by artificial heating of the air of the room. Of 223 patients so treated no case in the primary stage passed into the secondary and there were no deaths, and in only six instances did a second case develop in any house. In industrial areas, where a separate well-ventilated bedroom cannot be obtained, the patients were advised as to ventilation, and if capable of outdoor exercise were encouraged not to remain too much indoors. Drug treatment aimed at stimulating cough and increasing the flow of secretion, and, though vaccines may be of use theoretically in aiding the defensive mechanism of the body, in actual practice their usefulness is problematical. Doubt is expressed as to an attack of influenza predisposing to chronic illnesses, since, out of between 1,500 to 2,000 influenzal cases, only one instance of resulting chronic illness was observed.

331. Lilliputian Hallucinations.

RAOUL LEROY (*Journ. Nerv. et Ment. Dis.*, October, 1922, p. 325) calls attention to a new syndrome of visual hallucinations, Lilliputian in character, in which diminutive people are seen, together with animals and objects, all proportionately small in size, though seen quite apart from micropsia, the patient preserving a normal conception of surrounding objects. It is a veritable Lilliputian vision such as that created by Swift in *Gulliver*, the hallucinations being mobile, coloured, and generally multiple, and usually accompanied by a pleasurable and amused state of mind in watching the antics, as opposed to the majority of visual toxic hallucinations, which produce a painful impression. Occasionally the small people are heard to speak, though it is unusual for auditory hallucinations to coexist with visual. The individuals of this little world are generally seen in bright colours, walking, running, playing, and working in relief and perspective, and giving an impression of real life. The syndrome may occur in any mental malady, and it is met with in the febrile delirium of typhoid, cholera, erysipelas, pneumonia, or empyema, and in chorea and other infections, and especially in intoxications by alcohol, ether, cocaine, or hashish. Opium does not give rise to the phenomena. Apart from infections and intoxications, the condition has been observed in arterio-sclerosis, senility, fasting and inanition, and in dementia; it may exist apart from any mental malady, and such Lilliputian visions are not rare in dreams. Several instances are cited, both from experience and from general literature, showing the extremely varied character of the scenes, and of the dress and actions of the actors which may appear.

332. Arterial Hypertension.

P. LEREBoullet and JEAN HEITZ (*Paris Méd.*, July 1st, 1922, p. 6), in the course of their annual review of diseases of the heart and blood vessels, refer to Paillard's discovery that hypertension is relatively frequent in women who have undergone oophorectomy. Among 25 women who had persistent high blood pressure, 12 had had oophorectomy

performed, and 2 others had received x-ray treatment for fibromyoma. In another series of 31 patients who had had hysterectomy performed, 13 had symptoms of hypertension, most evident in 3 cases. Ovarian opotherapy had no effect in any of these patients. Heitz confirms Paillard's statements from his observations of 208 women, 48 of whom had been treated for fibromyoma. The authors do not agree that all cases of hypertension are secondary to renal disease, but think that the sudden arrest of hæmorrhage in these cases is an important factor. They suggest that radiotherapy in regulated doses may be preferable to surgical treatment, and observe that such cases should be watched for several years. They refer to de Meyer's researches on the importance of the "pulse pressure"; they distinguish the cases showing an increase of oscillation between the systolic and diastolic pressures, as the former rises, from those more numerous cases in which the "pulse pressure" is reduced; they point out that this should prove an important aid to prognosis. The authors discuss the treatment of hypertension, and after alluding to the use of several benzyl compounds they recommend "are lamp" treatment and especially diathermy by Duheim's method—two large metallic electrodes are applied directly to the skin and a high-frequency current of approximately 1,800 thermic milliamperes is passed for twenty minutes; in 14 cases out of 15 treated thus they have observed a distinct fall of blood pressure with relief of the cerebral and cardiac subjective symptoms.

333. Jaundice in Typhoid Fever.

A. S. VAN HEUKELOM (*Nederl. Tijdschr. v. Geneesk.*, August 19th, 1922, p. 801), who reports 2 cases, remarks that jaundice is one of the rarest complications of typhoid fever. Murchison saw only 1 case, Giesinger among 600 typhoid patients saw 10 cases (including cholelithiasis), Biermer among 695 patients saw 1 case, Liebermeister among 1,420 patients saw 26 cases, and Osler among 500 patients did not see a single case. Among 1,500 cases of jaundice observed at the front by Garnier and Reilly there was only one due to *B. typhosus*. Lenbe states that the presence of jaundice in a doubtful case is against typhoid fever. The first of van Heukelom's cases was that of a man aged 42, who, after feeling out of sorts for a few weeks, developed some jaundice with pain in the muscles suggestive of spirochaetosis icterohaemorrhagica. Although most of the characteristic symptoms of typhoid fever were absent—namely, clouded sensorium, intestinal manifestations, enlargement of the spleen, rose spots, bronchitis, positive diazo-reaction, and agglutination—the blood culture was positive on two occasions and the temperature and pulse were typical. The liver was much enlarged and the faeces were not acholic. Van Heukelom concludes that the patient was suffering from acute hepatitis and cholangitis caused by *B. typhosus*. The second case, in which jaundice was a mere coincidence unconnected with typhoid fever, occurred in a man aged 19, in whom the disease began with symptoms of acute obstruction of the bile passages—namely, jaundice, acholic faeces, enlargement of the liver and gall bladder, tenderness of the liver, and colic. Four days after the onset of jaundice he vomited an ascaris after a violent attack of colic and the jaundice then subsided. The possibility of typhoid fever, however, was suggested by the high continued fever, with relative bradycardia and the positive diazo-reaction, and the suspicion was confirmed by a positive blood culture. The disease then ran its course like an ordinary attack of typhoid fever, being subsequently complicated by pneumonia of the right lung, intestinal hæmorrhage, bilateral parotitis, periostitis, and right otitis media. Recovery took place.

334. Treatment of Skin Diseases by Potassium Permanganate.

S. FELDMAN and B. F. OCHS (*Arch. Derm. and Syph.*, August, 1922, p. 163) speak very highly of the value of solutions of potassium permanganate as a curative agent in dermatological practice. Their attention having been directed to the good results obtained by this drug in a severe case of eczematoid ringworm, they have given it an extensive trial in many similar conditions. In early moist and irritated lesions it should be used diluted to 1 in 5,000, whereas in lesions associated with deep infiltration and lichenification it may be employed as a saturated solution. Potassium permanganate has yielded better results in the treatment of epidermophytosis than any drug or combination of drugs hitherto employed. Cases of intertrigo of the mammary folds and on the upper thighs yield readily to very dilute solutions, while in the intertrigenous type of epidermophytosis occurring

between the fingers and toes stronger solutions may be employed with equally good results. In eczema variegatum good results are obtained by wet dressings, and, in old lesions, by painting with strong solutions of the drug. In eczematoid ringworm far better results are obtained by this method of treatment than with the use of Whitfield's ointment, but these cases require a longer period of treatment in order to obtain a cure than those mentioned above, and the treatment must be kept up a long time after the disappearance of the lesions in order to make the results permanent. The dysidrotic form is the most resistant to treatment, especially in the presence of deep-seated vesicles and a thickened epidermis. Even here good results are obtained after the lesions are prepared by some keratolytic agent. The manner in which the drug acts in the fungus diseases has not been ascertained, but from clinical observation there seems to be an indication that the beneficial action takes place by means of changes produced in the cells of the epidermis rather than by the direct action of the drug on the fungus.

335. Tuberculosis in Country Districts.

A. TURNO (*Il Policlinico, Fed. Prat.*, June 15th, pp. 809, 843) states that one of the most serious and distressing public health questions since the war is the spread of tuberculosis in the rural districts of all highly civilized countries. From his experience at Reggio Emilia he does not hesitate to affirm that 50 per cent. of his patients, two-thirds of whom live in the country, are suffering from tuberculosis. Many of these are cases of inelapient apical disease, but there are also examples of advanced pulmonary tuberculosis. The disease was much more widely spread among females than among males, owing to overwork, excessive fecundity and prolonged lactation, and to early loss of teeth, while, by giving rise to gastric trouble, rendered them less able to resist infection. Another important cause of the predisposition of country people to tuberculosis is the spread of alcoholism. Lastly, the consumption of unboiled milk has some etiological importance. While in towns milk is usually boiled before drinking, in the country this practice is generally neglected.

336. Horse Serum Treatment of Pyelitis and Pyuria.

D. M. COWIE (*Amer. Journ. Dis. Children*, September, 1922, p. 179) relates experience in the treatment of a number of cases of pyuria with horse serum (foreign protein). Some of them were, probably cases of pyelitis, but in only two of the cases was this proved by cystoscopy, by which method alone is it possible to diagnose pyelitis positively. In the first case horse serum injected subcutaneously cleared up a long-standing pyuria which had obstinately resisted the usual methods of treatment, the pus completely and permanently disappearing after the third injection, and from control experience in several cases it was found that horse serum frequently cleared up a refractory case. Intravenous injection of dead typhoid and colon bacilli produced no effect in a few cases which subsequently responded to treatment with horse serum subcutaneously, although horse serum intravenously induces reactions analogous to those of dead typhoid bacilli. That the effect does not depend upon hyperaemia as the result of hyperallergy is suggested by the fact that beneficial results sometimes occur with the first injection ahead of the development of the symptoms of serum disease, and it is impossible to say whether it is the protein of the horse serum, or the ant substance, or the combination of both that produces the result. The cases are reported rather from the standpoint of developing knowledge of the action of non-specific foreign protein in disease than with the idea of advocating the general adoption of this method of treating infections of the genito-urinary tract.

SURGERY.

Horseshoe Kidney.

337. SIXTEEN cases of horseshoe kidney seen at the Mayo Clinic, and which required operation, are analysed by E. S. JUDD, W. F. BRAASCH, and A. J. SCHOOL (*Journ. Amer. Med. Assoc.*, October 7th, 1922). In seven there was hydronephrosis; in six of these the diseased segment was removed, and in the seventh the isthmus was divided and the diseased kidney rotated in order to permit the ureter to lie in the normal position. One patient died; the others recovered rapidly from the operation. Four are now perfectly well—1 eight years, 1 four years, and 2 one year after operation. The formation of stone is common. Eight patients of the series were operated on for renal calculi, which in most cases were removed through a lumbar incision. There were no deaths. Three patients are perfectly well—1 five years and 2 two years after operation. Two patients are in excellent

health, but still have occasional dull pain in the lumbar region—1 four years and 1 one year after operation. One patient was well four months after operation, but the urine still contained pus. One patient, seven months after operation, had not had a recurrence of renal colic, but dysuria and frequency continued. In one case, heminephrectomy for tuberculosis was followed by a good result. In spite of complications, the results of the operations on fused kidneys have been quite as good as similar operations on normally developed kidneys.

338.

Vaccines in Osteomyelitis.

A. V. BEUST (*Schweiz. med. Woch.*, August 31st, 1922, p. 869) considers it unwise to temporize with vaccine treatment in the early stage of acute osteomyelitis, when operative treatment is imperative if general sepsis and other complications are to be avoided. But, as a supplement to operative treatment, vaccines may prove beneficial, and at the author's hospital during 1919 and 1920 46 cases of osteomyelitis have been treated, of which 23 were acute. In 6 acute and 9 chronic cases vaccines were given, an antigenous vaccine containing 500 million germs per cubic centimetre being preferred to polyvalent vaccines. Only 50 million germs were given at the first injection, and when this gave rise to no alarming symptoms, twice this dose was given after three or four days, and a dosage of 10,000 million was reached in some cases. As in all the acute cases this treatment was supplemented by incisions and drainage, it was difficult to form an estimate of its value, but it was noteworthy that all these acute cases terminated in recovery after treatment lasting one to five months. Only in 2 cases did it seem obvious that the vaccines played an important part in the patient's recovery, and though the author's enthusiasm for this treatment is mild he has sufficient faith in it to continue its use.

339.

Vaccine Therapy in Oto-rhino-laryngology.

A REVIEW, including many of their own observations, on the value of vaccine treatment in diseases of the nose, ear, and throat is furnished by J. BALDENWECK, M. JACOB, and A. MOULONGUET (*Arch. Internat. de Laryngologie*, July-August, 1922, p. 785). Their most striking results have been obtained in the case of boils—especially repeated attacks—and phlegmonous tonsillitis. In the former malady they employ for preference antigenous vaccines, which they give in very large doses—up to 6,000 million at a time—giving the injections at intervals of two or three days. On the other hand, in phlegmonous tonsillitis they resort to intravenous administration of stock vaccines. Their actual technique is not described at all in detail, nor the composition of the bacterial emulsion they used, which appears to have been prepared by a colleague. Of 14 cases which they treated 11 resolved spontaneously, while in 1 the remainder the abscess burst of its own accord. As their convictions are so strong on the efficacy of their therapeutics, it is to be regretted that their account is so lacking in precision. With chronic colds, mucopurulent rhino-pharyngitis, ozæna, and tubal otorrhœa they have had several successful results; in chronic sinusitis failures have been frequent; while in otitis media—both acute and chronic—they regard vaccine treatment with some degree of disfavour, many of their cases having subsequently developed mastoiditis. Their general conclusions are that vaccine therapy cannot replace operative treatment, though it may be employed as a very useful adjunct to the latter.

340.

Gonococcal Arthritis.

DE BARZY (*Bull. et Mém. Soc. Chir. de Paris*, June 27th, 1922, p. 888) discusses the merits of surgical treatment by arthrotomy, suture without drainage and early mobilization, and the advantages of intra-articular injections of serum. The latter method is most satisfactory, but may fail on some occasions. In articulations such as the wrist the injection may be easy when the joint is swollen, but later it becomes difficult and may be impossible; or, again, synovitis of the tendon sheaths may accompany the joint lesion, on which it has little or no effect. On other occasions the gonococci may be of a type very resistant to the injections of serum. In some cases the injection is painful after the second or third inoculation and the joint becomes intolerant of the serum; the articulation swells up and the patient is attacked with malaise, vomiting, and rise of temperature. These phenomena continue till the joint is emptied of its contents. Usually a thick liquid is found containing the unabsorbed serum, polymorphous cells, and no bacilli. If, therefore, the joint shows itself intolerant to the serum treatment and the patient exhibits signs of fever it is advisable to stop the injections and to empty the joint. Surgical treatment should then be adopted without further delay; this, though a little more complicated, is usually quite successful.

341. Post-Operative Beri-beri.

O. SCHNEIDER (*Zentralbl. f. Chir.*, September 16th, 1922, p. 1357), who was formerly attached to the Chulalongkorn Memorial Hospital, Bangkok, records four cases of post-operative beri-beri which ended fatally, as well as others which recovered. Although all the patients did not give a previous history of beri-beri it is probable that those who did not had had mild attacks which were not diagnosed, and that the disease was present in a latent form. A feature common to all the patients in addition to the employment of chloroform anaesthesia was that the operation had been carried out during the cold season of the year when the natives' resistance was lowered and the development of post-operative beri-beri was favoured. Recent infection with beri-beri in the hospital could be excluded in all the cases. The variety of beri-beri observed was exclusively the vagus form, in which the heart, lungs, and stomach are principally involved, as was manifested by a diminution in the tone of these organs. The other forms of beri-beri, such as the dropsical, atrophic, scorbutic, and paralytic forms, were not observed after operations. Schneider is inclined to attribute the occurrence of beri-beri mainly to chloroform, first because it has the property of affecting the heart and respiration, and secondly because the symptoms observed were referable to these organs. In any case he is convinced that in patients who have once had beri-beri chloroform and operations, especially during the cold season, act as an exciting cause of an attack. Since he has taken the precaution of making a careful inquiry for a previous history of beri-beri, and on the slightest suspicion of it using local anaesthesia with novocain, he has not had a fatal case of post-operative beri-beri.

342. Surgical Diathermy for Inoperable Growth of the Upper Air and Food Passages.

C. E. J. PHILLIPSON (*South African Med. Record*, June 24th, 1922, p. 222) calls attention to the advantages of surgical diathermy when operation is contraindicated; it is practically bloodless and non-productive of shock, while it sterilizes the tissues, blocks lymphatics, and prevents dissemination of cancer cells, frequently relieving pain, and minimizing the occurrence of septic pneumonia. Its disadvantages are that it destroys healthy and diseased tissues alike, that secondary haemorrhage may result from the walls of adjacent vessels becoming softened, and that keloid may occur when the skin is involved. Heat is generated within the tissue, instead of being spread, as in the actual cautery, by conduction from a heated metal, a coagulation of the tissues *in situ* being produced, which is of greater extent than that caused by the actual cautery. For inoperable growths of the larynx and pharynx it is advisable to do a preliminary tracheotomy, and to pass an oesophageal feeding tube immediately after diathermic treatment, since the parts around the coagulated areas swell, and there is always a profuse exudation of lymph. Small malignant ulcers without palpable glands were operated upon under local anaesthesia, but in extensive operations infected glands were removed and the external carotids, or the several branches, ligatured a week or ten days beforehand. Although this latter procedure by starving the area of the growth delays the rapidly with which the slough is extended, this is more than counterbalanced by the diminished risk of haemorrhage. In all cases the mouth and teeth are carefully prepared for days in advance, to eliminate as far as possible the introduction of sepsis, and it is advisable for the operation to be followed by a course of x rays to the area for a few weeks.

343. Buccal Actinomycosis.

R. GÉZES (*Rev. de laryngol., d'otol. et de rhinol.*, June 30th, 1922, p. 490) reports an unusual case of actinomycosis of the throat. The patient, aged 52 years, commenced with slight pain in the throat; this continued for two or three days and caused no anxiety. Four days later the patient complained of general malaise and rise of temperature, the throat being inflamed and swollen; the voice was hoarse and speech became painful, and later there was general oedema of the fauces and submaxillary swelling. Bacteriological examination at this time showed diplococci in chains and many polymuclear cells. His condition became worse, and a kind of pseudo-membrane covered the fauces. Bacteriological examination at this stage, eleven days after the onset, showed the predominance of the mycelium of actinomycosis. Treatment with large doses of iodide led to a rapid improvement in the patient's condition. This observation is interesting as the condition is unusual, and there was little to make one think of actinomycosis. Actinomycosis is characterized by its slow development and the typical yellow granules. In this case brownish liquid was obtained on puncture of the swelling, and the rapid course resembled rather an acute infection. It should therefore be borne in mind that a swelling at the back of the pharynx with a rapid onset, similar to angina, may be an actinomycotic infection.

OBSTETRICS AND GYNAECOLOGY.

344. Adeno-carcinoma of the Fundus Uteri.

J. V. MEIGS (*Amer. Journ. of Obstet. and Gynecol.*, September, 1922, p. 241) analyses the clinical and pathological findings in 44 cases of carcinoma growing in the uterine cavity above the internal os, whether springing from the surface or the gland epithelium. The average age of the patients was 50 years, but fifteen patients were under that age; about three out of four had had children. As many as 5 per cent. had not passed the menopause, and thus presented greater difficulty in diagnosis than other cases. The first symptom of the tumour appearing before the menopause was menorrhagia or metrorrhagia. Discharge—at first thin and watery, but later foul, irritating, and blood-tinged—occurred before the bleeding in cases after the menopause, but after the bleeding in cases before the menopause. Pain was by no means a constant sign, and cachexia was not generally noted. Loss of weight occurred in 8 only of the 44 cases, and 7 were gaining weight. The writer remarks that symptoms are present very early in the disease, but appearing about the time of the menopause are often overlooked and indeed attributed to the menopause. He adds that patients with abnormal bleeding or discharge about this time, even if no other symptoms are present and a thorough physical examination is negative, should be submitted promptly to intracervical examination and diagnostic curetting. In over one-half the cases of the series the diagnosis was made or suspected before operation or intrauterine exploration. Microscopic diagnosis from "gland hypertrophy" presented difficulty in some cases. A condition frequently confused with carcinoma of the uterine body was atresia of the cervix, leading to intermittent bloody infected discharges. Five years or more after operation, 62.5 per cent. of the cases were free from recurrence. The operation recommended is complete hysterectomy (not Wertheim's operation) with removal of the adnexa of both sides.

345. Thyro-parathyroid Insufficiency and Pregnancy.

A. FRUHNHOLZ (*Gynecol. et Obstét.*, 1922, vi, 3, p. 146) discusses, on the basis of four personal cases taken in conjunction with a survey of the literature, the connexion between pregnancy and insufficiency of the thyroid and parathyroid glands. Partial thyroidectomy has in many instances been followed by no harmful appearances during gestation, whether this occurred after or had begun before the operation; in a number of cases, however, convulsions, tetany, and albuminuria have followed, and have recurred in succeeding pregnancies. According to the author, the thyroid hypertrophy whose occurrence is the rule from the fifth or sixth month of gestation onwards is absent in about 19 per cent. of subjects; these women are in a condition of relative hypothyroidism, and nine out of ten of them become albuminuric. Habitual hypothyroidism is accompanied by dysmenorrhoea and menorrhagia; and Hertoghe was probably right in regarding many cases of repeated abortion during the early months in non-syphilitics as due to thyroid deficiency, and as curable by exhibition of thyroid substance. Sabouraud, Falta, and others have reported falling of the hair, cutaneous thickening, and even frank myxoedema first appearing in connexion with pregnancy. With regard to the effect of pregnancy supervening in those already the subjects of hypothyroidism, disappearance during pregnancy of migraine, chronic rheumatism, and asthma—attributed to minor thyro-parathyroid deficiency—has been observed in some instances. Fruhnholz describes the course of pregnancy in four patients showing indubitable stigmata of a moderate degree of long-standing or congenital thyroid inadequacy. Two had eclampsia with slight albuminuria, one albuminuria, and one pregnancy oedema; two gave birth prematurely to dead foetuses. Pregnancy in moderately severe cases of myxoedema, though comparatively infrequent, is not so rare as might be inferred from a study of the literature. Tetany is found very frequently in connexion with pregnancy, the puerperium, or lactation, all of which probably may be regarded as having thrown extra burdens on parathyroids which were already relatively insufficient. It is significant that these cases are accompanied by an increased excretion of calcium at a time when calcification of the foetal skeleton demands an unusual degree of activity of the maternal calcium metabolism.

346. Pregnancy and Carcinoma of the Cervix.

In the experience of SCHWEIZER (*Zentralbl. f. Gynäk.*, September 30th, 1922, p. 1586), cervical carcinoma is encountered in about 0.05 per cent. of pregnancies, and attacks more frequently those who have had many children, especially in rapid succession. In many cases it is difficult to decide as to whether the gestation antedates the cancer or vice versa. The case having once come to examination, diagnosis.

presents little difficulty, but, with regard to subjective signs, haemorrhage occurs late, is rarely if ever profuse, and may be absent. Slowing of the rate of growth of a carcinoma during pregnancy was not observed. The malignant disease affects the course of gestation by predisposing to premature labour, and of labour by favouring tears and interfering with dilatation of the cervix; infection is exceptionally liable to occur before, during, or after birth. Prognosis is more unfavourable in those cases in which the carcinoma makes its appearance shortly after termination of pregnancy—the so-called puerperal carcinoma. Of the author's cases, 82 per cent. were operable. The treatment advised is, for inoperable cases, symptomatic measures combined with x-ray therapy, followed at term by abdominal hysterectomy and supravaginal amputation of the uterus with extraperitoneal fixation of the cervix: for operable cases, wide hysterectomy, preceded, if the child be viable, by Caesarean section. In pregnancies which have reached their latter half, however, the prognosis is somewhat better after radium treatment than after Wertheim's hysterectomy; against the former is the sacrifice of foetal life and the risk that dense scars may be left behind.

347. Cervical Carcinoma after Supravaginal Hysterectomy.

R. T. FRANK (*Surg., Gynecol., and Obstet.*, September, 1922, p. 334), in discussing the indications for total or supravaginal hysterectomy for myoma, comes to the conclusion that although 256 cases of cancer developing in the cervical stump after the latter procedure have been recorded from American sources alone, it is unwise to advocate total hysterectomy as the routine operation. Even total excision of the cervix may be followed by cancer of the vaginal vault, stump cancer follows amputation for conditions other than myoma, and the mortality of total hysterectomy is higher than that of supravaginal removal. "Coring out" the cervix, as recommended by Kelly, may be of service and does not add to the operative risk. Before operation minute examination of the cervix (a speculum being employed), together with removal of a piece of any suspicious area for microscopical examination, should be carried out. A case is reported of cancer noticed in the cervical stump five months after supravaginal hysterectomy for uterine myomata, and presumably overlooked at the time of operation: an unusual feature was that a small metastatic focus was found in the tip of the vermiform appendix, which was free and had no direct connexion with the growth.

PATHOLOGY.

348. The Pathological Significance of Abnormal Leucocytes in the Blood.

A SUMMARY is given by J. SABRAZES (*Gaz. hebdom. des Sciences médicales de Bordeaux*, October 8th, 1922, p. 481) of his report to the sixteenth French Congress of Medicine in Paris on the subject of the diverse morphology of white cells encountered in the blood stream. After referring to the normal genesis of the leucocytes and describing the various types of mother cells from which they are derived, he proceeds to the consideration of their abnormalities. These he classifies under five headings: (1) Degenerating cells, such as are met with in septicaemias, intoxications, leukaemias, etc.; these show leucolysis, pyknosis, degenerative cytoplasmic granules, excessive lobulation of the nucleus, fatty infiltration and degeneration, iodophilia, etc. (2) Immature cells, the product of a physiological cytogenesis; examples are met with when the bone marrow is stimulated to rapid output, and include the myeloblasts, myelocytes, megakaryoblasts, etc.; similarly, immature forms of lymphoid cells are included in this category. (3) Abnormal cells derived from an atypical cytogenesis; among these are the large, undifferentiated types of lymphoidocytes, Rieder's lymphocytes, polymorphonuclears with ba-ophile inclusions, cells with abortive mitoses, etc. (4) Degenerative forms of cells which are abnormal either through simple immaturity or through a deviation in their evolution; such cells result from the occurrence of cytoplasmic or nuclear fragmentation in cells which are already profoundly altered, and are seen to contain protoplasmic masses of basophilic, neutrophilic, or eosinophilic reaction; as examples, the cells of Türk are cited. (5) Cells usually foreign to the blood, such as tumour cells.

349. Pure Cultures of Large Mononuclear Leucocytes.

A. CARREL and A. H. EBELING (*Journ. Exper. Med.*, October, 1922, p. 365) have isolated large mononuclear leucocytes from the blood of a hen and cultured them, maintaining them in an active condition for nearly three months. The blood was collected in paraffined tubes and centrifuged; after removal of the plasma a few drops of diluted embryonic tissue juice

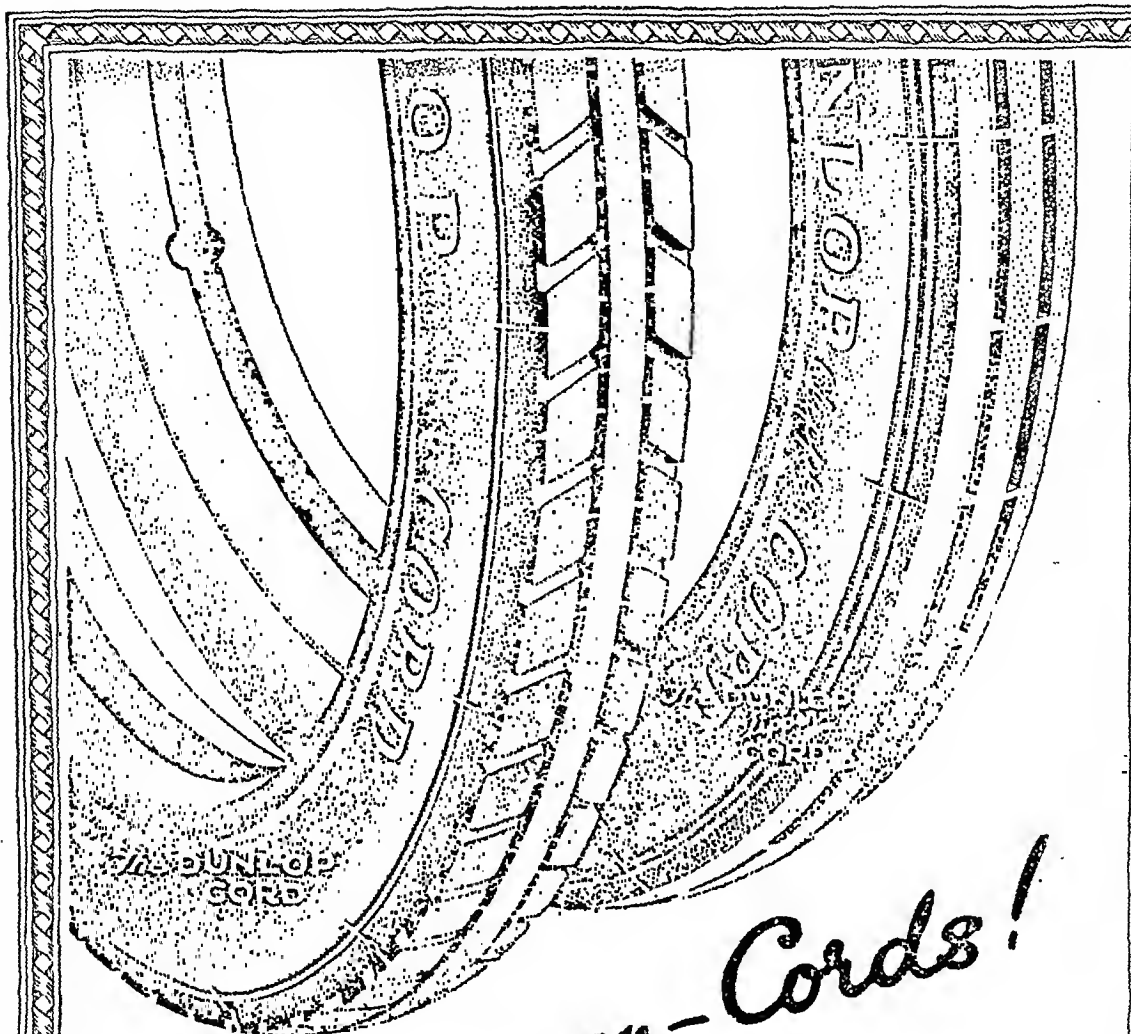

were placed at the surface of the coat of leucocytes and fifteen minutes later the coagulum containing the white cells was removed and placed in a watch-glass with a small amount of Ringer's solution. After washing away the red cells, small fragments were selected and taken from the fluid with the point of a cataract knife. Cultures were made in a medium composed of plasma alone, of plasma and Tyrode solution, or in media composed of plasma and chick embryo juice. The culture medium was placed in a cover-glass of mica and a small fragment of the leucocyte film was embedded in it before coagulation, care being taken that the leucocytes embedded in the medium were neither too few nor too many in number. When the culture was properly prepared, a great many amoeboid cells were seen in the medium after twenty-four hours. For subculture the invaded coagulum was divided into several fragments with a very sharp knife and the cells migrated into the new medium. After the first passage the transfer into a fresh medium was made every forty-eight hours and then every third, fourth, and fifth day. The cultures were examined while living and drawings and photographs were made of the cells, of which many illustrations are reproduced. In these cultures the large mononuclears became transformed into cells which assumed the appearance of fibroblasts, forming spindle-shaped or stellate cells, with long and slender processes uniting sometimes in a reticulum with those of other cells. The mononuclears migrated and proliferated at a slower rate than similar cultures of fibroblasts, than which they were much less resistant. It was found that the activity of the large mononuclears was increased by embryonic tissue juice and inhibited by homologous serum.

350. Situation of Malaria Parasite in Relation to Red Cell.

J. A. SINTON (*Indian Med. Gazette*, October, 1922, p. 366) supports the view, originally put forward by Dr. Mary Rowley-Lawson, that the malaria parasite is attached to the outer surface of the red cell and is not inside the cell, as maintained in most descriptions. Working with subtertian malaria infection, Sinton distorted the shape of the red cells by rendering the blood hypotonic, and also, in a second series, hypertonic; films, stained in the usual way, showed the malaria parasites often attached to the edge of the red cell. Applying the same methods to benign tertian infection the parasites were seen apparently extracellular running along the margin of the cells, often with their pseudopodia extending on to the surface. Blood was also taken directly from the finger and allowed to drop in fixative solution, after which the cells were dehydrated, embedded in paraffin, and sections cut, and stained with Giemsa. When these sections were examined the parasites could be seen, on careful focusing, to be on a different plane from the host cell and to be attached apparently either to its upper or lower surface. It is only by such means as this that the real situation of the parasite can be determined, for when an ordinary blood smear is made the cells, on account of their flattened shape, tend to lie on one of their concave surfaces, and when parasites are seen occupying one of these concave surfaces they would appear the same whether they were inside or outside the cell. If the parasite is extracellular the concave surfaces would appear to be points of vantage for the parasite because the concavity of the cell would afford the parasite a certain amount of protection against the dangers of being rubbed off by the other blood cells as they flow past in the circulation before it has obtained a firm hold on the host cell.

351. Extirpation of the Pineal Gland.

IN spite of the difficulty in technique, C. I. URECHIA and C. GRIGORIU (*C. R. Soc. Biologie*, July-September, 1922, p. 815) have successfully removed the pineal gland from a couple of cocks, and have been enabled to study the changes subsequently ensuing. After the operation the birds presented an involution of the secondary sexual organs lasting approximately for two months; when this period had elapsed growth set in rapidly, and the development of these organs became well marked. Eight months after the extirpation of the gland the animals were killed. They presented on inspection no difference from the controls of the same generation. The weight of the testicles was the same, but the interstitial tissue was in greater abundance in the operated animals. As regards the pituitary, this gland was found to be considerably enlarged, being about three times the size of that common to normal cocks. On microscopical examination it was possible to substantiate an increase in the acidophilic cells, the presence of numerous acini filled with acidophilic colloidal material, and a simple hypertrophy of the nervous lobe. The conclusion is drawn from these two experiments that the result of the removal of the pineal gland was to increase the size of the pituitary, and probably to stimulate its function.

From now on—Cords!

—because no other type of tyre is equal to the strain of present-day motoring.

Canvas tyres served a good purpose—but that was yesterday. To-day's demands on tyres are greater.

Dunlop Cord tyres are the tyres of to-day.

See the two new types, at the Motor Show—the Dunlop Cord and Dunlop Clipper Cord. They are the answer to to-day's demands.

A British Medical Association Lecture

ON

CARDIAC FAILURE.

DELIVERED TO THE NORTH WALES BRANCH, JULY 11TH, 1922,

BY

JOHN HAY, M.D., F.R.C.P.,

HONORARY PHYSICIAN, ROYAL INFIRMARY, LIVERPOOL.

In the management of patients suffering from acute fevers, from valvular disease, from persistent high blood pressure, and from progressive arterio-cardio-sclerosis, the medical man is always on the alert for the first sign of cardiac failure, for he knows that in such patients the power of the myocardium tends to fail, and must be maintained.

There is apparently an inevitable tendency for every practitioner to drift gradually into a routine line of treatment when dealing with this constantly recurring difficulty; the variable nature of the measures employed indicates a lack of any sure or solid basis for our medication. We are all creatures of habit and amenable to auto-suggestion, with the inevitable result that our critical faculties become dulled in relation to the results obtained by any routine line of treatment. As an example of this I would remind you of what is known to you all—that for many years the recognized treatment of shock was the hypodermic injection of strychnine. This practice was followed, year in, year out, by men who were satisfied that they were obtaining good results; until Crile proved that instead of strychnine being helpful and curative in such a condition it was definitely harmful and noxious. Now its use is abandoned by all competent men.

The present position in relation to cardiac failure is unsatisfactory—first, because there is a disinclination to face the necessity present in each case of determining the exact cause of the failure and adopting the treatment to meet the special need of that patient; and secondly, because there is not a clear conception as to the real value and therapeutic action of the various drugs used.

There can be no doubt that some of these drugs have a wholly fictitious reputation and yet continue to be administered with a simple and blind faith, to the mutual satisfaction of both the doctor and his patients. The doctor is not only cocksure that his treatment is right, but he is equally cocksure that whatever improvement follows is due to his interference. The teachings of tradition and a pure empiricism must yield to a more scientific attitude in the practitioner if advance is to be made.

Persistence in the use of a drug or drugs which are inert, or even really harmful, is hardly credible if one did not recognize the immense difficulty experienced in estimating the result of treatment. Human nature is more than predisposed to associate any satisfactory change in the patient with whatever method of treatment had been used immediately antecedent to that change.

When discussing such a problem as cardiac failure it seems essential to have a clear conception of what is meant by the term. An efficient heart is one which maintains a normal circulation, which supplies the muscles and viscera easily with the blood essential to their healthy functioning, and which possesses a reserve power adequate to meet the varying stresses of daily life.

We know that the demands made on the heart are greater in one man than in another, and that there is a correspondingly wide difference in the actual power of different hearts—hearts which are nevertheless healthy in themselves and adequate for the purpose of that individual. Failure begins when a heart ceases to respond adequately to the normal calls upon its reserve power, when it fails to rise to the occasion.

THE RESPONSE OF THE HEART TO EFFORT.

It will be helpful to review the manner in which the normal heart responds to effort, for the more clearly we grasp the essentials of the wonderful mechanism by which it meets the calls made upon it, the more easily shall we understand the symptoms of cardiac failure and the treatment.

It is to furnish an adequate supply of blood to the capillary bed, to maintain the leisurely passage of oxygen-bearing corpuscles through the ultimate ramifications of the circulation. The blood has one primary duty—

namely, that of acting as an oxygen carrier—and there is direct relation between the consumption of oxygen by the tissues and the amount of work done. Physical effort at one increases the need for oxygen, and this peremptory demand of the tissues has to be met by an increased flow of blood. The response of the heart is immediate and adequate, the output of blood per minute is doubled, trebled, or even quadrupled. Instead of 3 to 5 litres a minute the output may reach 12 to 20 litres.

This marvellous response is the result of several factors of which the chief are an increase in the rate of the heart and a more powerful and efficient systole. The very impulses which stimulate the motor area of the cortex overflow to the vagus centre and lower its tone, and thus the heart's pace quickens even before the muscular effort has begun.

A mere increase in rate would not, however, increase the output of blood per minute unless there was corresponding increase in the return of venous blood to the heart. This is brought about by the augmented respiratory movements and also by the energetic contractions of the muscles themselves, which empty the veins and drive the venous blood on towards the right auricle. This increased supply of blood to the right auricle produces a slight rise in the diastolic pressure which reflexly lowers the vagal tone, with the result that the pace of the heart is still further heightened through the accelerator nerves. Coincidentally there is a definite rise in the systemic blood pressure and an increased flow of blood through the coronary arteries, which have dilated in response to the extra demands on the heart.

I have only touched on some of the more obvious changes associated with effort, but there are certain points which might be remembered, more especially in relation to the action of drugs.

An increase in rate is sometimes an indication that a weak heart is finding it difficult to supply an adequate output per minute. It indicates that the heart is attempting to counter-balance a less efficient systole by increased frequency. A more efficient systole increases the output per minute, even with an unchanged rate, provided there is a greater inflow. Dilatation of the coronary arteries, augmented by a rise in blood pressure, enables a better supply of oxygen to circulate through the myocardium.

Moderate effort in a healthy patient is not associated with any discomfort, but when excessive, two symptoms manifest themselves: (1) a tight feeling across the chest, a sensation as if it was impossible to expand the thorax; this may verge into pain; and (2) a sense of shortness of breath. Such symptoms appearing after great effort would be void of significance, but coming on after an amount of exercise which had previously been tolerated without discomfort would certainly point to a limitation of the reserve power—in other words, to early cardiac failure.

The first signs of cardiac failure are subjective; the later indications are objective and point to a serious degree of inadequacy. These earliest signs are of marked significance, for it is then that treatment may prove invaluable; discomfort going on to pain is probably of the greater importance among them, and it is this symptom which is most often misunderstood—partly because the patient's attitude towards it is misleading, and partly because it is difficult to get a clear account of his distress without a searching cross-examination.

CARDIAC PAIN, INDICATING CARDIAC FAILURE.

A common complaint is that of "indigestion," more usually after breakfast, and this indigestion is of the nature of a "lump behind the breast-bone," either at the level of the middle or lower third of the sternum. Associated with this there is sometimes flatulence. Attempts are made to bring up wind, and finally, after a sufficiency has been swallowed, a quantity is eructated with subsequent relief. The significant feature of these subjective sensations is that they are aggravated by effort, and that the "indigestion" is eased by rest. Instead of a "lump" there may be nothing more than a tightness of the chest on moderate effort, but frequently worse after a meal or intensified by cold. Such patients yearn for the sunshine and dread the north-easterly winds.

The subjective sensations may, however, be of a different character, such as an aching pain at the angle of the left scapula or pain in the left elbow or wrist or arm. These pains in the arm or shoulder are often said to be due to neuritis but here the origin is overlooked; their relationship to effort, and their persistence in pain, is definitely precordial or substernal in site, begins to manifest

self with accompanying dyspnoea. Another symptom the significance of which is important is a sensation of weight in the chest, more often the left, unaccompanied by any definite pain; with this there is an inability to carry parcels. Such a condition is not an uncommon sequel to an attack of frank angina pectoris, but may exist in the absence of any such history. Sensations comparable to the above are almost invariably intensified by increased exertion and yield to rest, and this characteristic should be sought for when in doubt as to the meaning of such aches and pains.

It is of the greatest importance to remember that a diagnosis of "pain, cardiac in origin, and evidence of cardiac ailment" must not be dismissed, as often happens, because physical examination of the heart fails to reveal any evidence of organic disease. The pain and discomfort are in themselves the evidence of the cardiac inadequacy, and fully justify such a diagnosis.

SHORTNESS OF BREATH.

This may be the first indication of a failing heart. It may be the only indication, but is often accompanied by some degree of precordial discomfort or actual pain. It is an early sign in those suffering from mitral stenosis and in patients with auricular fibrillation. Dyspnoea begins to be noticed by the patient when it is induced by a degree of effort which previously caused no distress; the limit of the reserve power is more easily reached.

The later signs of cardiac failure need only be mentioned. They are objective and indicate definite and unmistakable inadequacy. They include venous engorgement, a large distended liver, painful abdominal wall, especially in the right hypochondrium, cyanosis, oedema, ascites, progressive dilatation of the heart, and basal crepitations (hypostatic congestion).

A sign of some considerable significance is true alternation of the pulse. The pulse is regular in time, but alternates in volume and tension. The alternation may be of short duration, or it may be persistent. In rare instances this can be recognized on palpation of the radial artery, but alternation is most easily appreciated during the estimation of the blood pressure; if there are occasional premature beats it is more marked immediately after the occurrence of such a break in the rhythm. With a high blood pressure it may be observed before the subjective signs of cardiac failure have obtruded themselves on the notice of the patient, but usually some degree of cardiac dyspnoea and pain are present on any effort.

In the rapid action of paroxysmal tachycardia and auricular flutter it is a common phenomenon, and if the duration of an attack becomes prolonged it is usual for some degree of alternation to develop. Its appearance is an indication of failure of the myocardium, though it has not the same prognostic significance in patients suffering from tachycardia as in those with high blood pressure or arterio-sclerosis.

If after careful consideration of the subjective symptoms and other data it is recognized that some degree of cardiac failure is present, the question to be answered is, What is the underlying cause? There are various possibilities to be considered:

1. Myocardial inadequacy resulting from the effect of toxins, as in acute rheumatism, diphtheria, pneumonia, and influenza.
2. Myocardial damage, possibly syphilitic. Narrowing of the coronary arteries.
3. A steady persistent rise in blood pressure.
4. In cases of valvular disease, an increase in the degree of mechanical defect.
5. Persistent increase in rate: (a) paroxysmal tachycardia; (b) rapid irregular action in auricular fibrillation.

In addition there is what may be called circulatory failure—a lack of vasomotor tone—in which the cause of the circulatory failure is vascular rather than cardiac.

TYPES OF CARDIAC FAILURE.

We have, then, certain groups or types of cardiac failure that stand out at once for recognition.

I.

Failure due to toxæmia, in which the myocardium is definitely damaged by toxins, occurs, for instance, in influenza and diphtheria. The only treatment worth considering in such a case is antitoxic, and the preservation of the heart from all strain.

In diphtheria the use of antitoxin is indicated. In pneumonia within the first three days dextrotoxic vaccines find a place, and if the pneumonic infection belongs to Type I then

the intravenous injection of the corresponding serum is advisable; in addition, purgation and methods of keeping the skin active should be employed.

When the myocardium is damaged by an acute toxæmia the greatest care should be taken to save it from all avoidable effort and strain. The details of the nursing are all-important; anything impeding the respiratory movements of the chest and diaphragm should be dealt with at once—such as, for example, intestinal distension, which materially handicaps the heart by interfering with the normal descent of the diaphragm. A sharp pleural pain similarly limits the movements of the chest wall, and care should be taken that a pleural effusion is not overlooked. Drugs given in the hope of compelling the heart to act more efficiently are useless. For such a purpose the hypodermic injection of strychnine is futile and the value of digitalis questionable. Professors Dixon and Harvey in a suggestive paper¹ published in 1908 related some interesting experiments bearing on this point. One portion of their paper deals with the toxic effect of diphtheria, and the experiments reported justified the authors in the opinion that drugs act much less effectively on cells poisoned by toxins.

It is probable that toxins vary in their effect on the cardiovascular system. Consequently satisfactory treatment will depend on a knowledge of the peculiar action of the toxin in any particular disease. S. Yabe² has recently published the results of some experimental work on the action of diphtheria toxin upon the circulation. He found that the toxin produced a lowering of the blood pressure, due neither to cardiac failure nor to direct action on the peripheral vaso-constrictory nerves, but to failure of the central vasomotor mechanism. It is unfortunate that so little experimental work dealing with the action of drugs on the circulation in acute toxic conditions has been done, but what evidence there is lends support to the view that severe toxæmia diminishes very materially the response to drugs.

II.

There are the patients in whom the cardiac inadequacy is the result of progressive degenerative changes in the myocardium or in whom the coronaries are so narrowed that the blood supply to the heart muscle is just sufficient to meet the needs of an easy and placid existence.

In such patients the essential thing in treatment is not drugs but an adaptation of the patient's life to his limitations. It is obvious that drugs can only play a small part here unless there is some hopeful element in the history, such as syphilis. Syphilis is ill borne by some, for the patient is not alone who said, "I don't like Annie Domini, she is so persistent."

III.

We have also the group of high tension cases in which the heart begins to show signs of failure. I have noticed that these symptoms frequently date from an attack of influenza or other infection which impaired the driving power of the myocardium and materially diminished the cardiac reserve.

Here the regulation of exercise and diet, attention to the bowels, and especially the occasional use of mercury, either as calomel or blue pill, together with the exhibition of haematinics, are of the greatest value. Such measures are of more service than the so-called cardiac tonics, though the caffeine and theobromine group appears to be helpful, and opium in some form may prove invaluable in the later stages. The iodides have established a reputation in the treatment of this type of patient and may be given a fair trial, though it is difficult to explain the manner in which they act; there is certainly no evidence that they lower the blood pressure. Frequently vaso-dilators are useful, especially in warding off attacks of cardiac pain. A tablet of erythrol tetranitrate chewed a few minutes before leaving the house in the morning may enable a patient to reach his office in comfort. It neutralizes the slight rise in pressure caused by the effort and saves the heart, but it is most doubtful whether the persistent use of these vaso-dilators has any real and lasting effect on the blood pressure.

IV.

Obtronic valvular disease tends to progress and thus increase the mechanical defect, and there is also in most instances some impairment of the integrity of the myocardium. As in Type III so also here, cardiac failure may be precipitated by some passing febrile attack. There is a limit to the development of hypertrophy, and that limit is the calibre of the coronary arteries. Sooner or later, then, such patients

manifest signs of cardiac failure. A compensatory rapid action is induced by the slightest effort, accompanied by distress.

In the absence of a disorderly rhythm the treatment is primarily by rest, and an attempt to improve the quality of the blood by the administration of iron and arsenic over long periods—say for four to six months at a time.

V.

A most important group, if not the most, is that in which fibrillation of the auricle is responsible for the cardiac failure.

Auricular fibrillation is of common occurrence, and is characterized by a specific change in the activity of the auricular muscles. Sir James Mackenzie has recently suggested that this is the result of a loss of control on the part of the sino-auricular node and junctional tissues. The ventricles usually beat with increased rapidity; their action is disorderly, and many of the systoles fail to transmit a pulse to the wrist. This fundamental alteration in the mechanism of the heart adds materially to its difficulties, and sooner or later indications of cardiac failure show themselves. The first is usually an increased liability to shortness of breath.

The power to recognize the presence of fibrillation is of more importance from the point of view of treatment than the power to discriminate between the various forms of valvular disease. Once the existence of fibrillation is established the lines of treatment are clearly defined. It is in this group that drugs are of paramount importance, and the drugs are those of the digitalis group.

I do not propose to discuss the treatment of fibrillation in any detail, since so recently as July 22nd I dealt with the subject in the BRITISH MEDICAL JOURNAL, but it is necessary to refer to one or two points in the use of digitalis and its allies.

Intravenous medication is indicated when the cardiac failure is severe and the expectation of life is measured by hours—then strophanthin is the most efficacious remedy, and should be used in doses varying from 0.5 to 1 mg. Otherwise the ordinary tincture of digitalis (B.P.) is probably the best preparation. Nativelle's granules of digitalin 1/240 grain are also useful, and there are other standardized tinctures and extracts which have proved satisfactory.

Whatever preparation is used it should be pushed until a specific response is obtained, and the amount then reduced until the optimum dose for that individual patient is determined.

If the diagnosis of fibrillation is established, then by some means or other digitalis and its allies must be administered. Nausea and vomiting do not necessarily indicate that the drug has been given in excess; an irritable stomach must be circumvented either by greatly diluting the digitalis or strophanthin or by the simultaneous administration of a bland and soothing stomachic mixture. An intravenous injection may prove to be the only satisfactory method.

In auricular fibrillation and auricular flutter the rapid action of the heart can generally be controlled by drugs; the reverse is, however, the case in true paroxysmal tachycardia. The ventricle continues to beat at 200 or more in spite of all treatment, and gradually this great strain on the myocardium induces cardiac failure with progressive dilatation, cyanosis, and other objective signs. Drugs appear to have no influence on this type of tachycardia—neither strophanthin intravenously nor digitalis by the mouth. Opium in some form is the most valuable drug. Pain must be relieved and sleep obtained. In this way the power of the myocardium is best maintained.

VI.

It is perhaps as well to refer briefly to cardio-vascular failure, in which it is not the heart itself that is at fault, but either the terminal branches of the vessels are affected or the vagal tone becomes appreciably raised, producing slowing and a tendency to syncope.

Cardio-vascular failure is found in severe toxæmias such as diphtheria, and also in post-traumatic and post-operative shock (surgical shock). Bayliss has shown that in these patients the mass of the blood in currency is greatly diminished. There is exæmia, "an accumulation and stasis in capillary areas," with a consequent fall in blood pressure. This fall in blood pressure must be met. Bayliss demonstrated that intravenous injections of 6 per cent. gum arabic in normal saline raised the pressure at once and rapidly improved the condition of the patient.

This applies to surgical shock associated with loss of blood. Unfortunately there is not the same favourable response in patients suffering from post-operative shock in which there has been little, if any, bleeding. Adrenaline or pituitrin should be injected, and it is usual to use, in addition, intravenous injections of normal saline and to give saline enemata. Similar lines of treatment should be followed in conditions of severe toxæmia.

A sensation of faintness or actual syncope is due in part to increased vagal tone, and this is best countered by hypodermic or intravenous injections of atropine in full doses. In such patients the pulse rate falls and the volume of the pulse is diminished; in fact, in some instances it may cease to be palpable at the wrist. There is a fall in blood pressure of a degree not to be explained by vagal action alone.

Such faints are not an indication of either heart disease or even of primary cardiac failure; they are reflex, and are probably a combination of undue vagal slowing and a lowering of vasomotor tone.

Drugs.

In cardiac failure drugs, etc., may be used:

- (1) To influence the nervous system (opium, chloral, bromides);
- (2) To improve the quality of the blood by increasing its hæmoglobin content;
- (3) To neutralize toxins;
- (4) To stimulate the myocardium to more vigorous contraction;
- (5) To depress the junctional tissues and slow the ventricular rate;
- (6) To raise the blood pressure.

Before concluding I propose to discuss in a little more detail some of the drugs more commonly administered as cardiac stimulants or toxins.

Strychnine.—I have already referred to the uselessness of strychnine in cases of shock, but there can be no doubt as to the widespread faith in its action as a direct cardiac stimulant. There is little satisfactory evidence that strychnine given in the doses usually employed has any action at all on the circulation. Drs. Parkinson and Rowlands carried out a careful series of observations of 50 patients, and their considered opinion is as follows:

"We found no evidence that the subcutaneous injection of a full dose of strychnine in cases of heart failure with a regular rhythm produced any change in the blood pressure, rate of pulse, rate of respiration, or general symptoms, within an hour following its administration. In cases of auricular fibrillation strychnine produced no change in the rate or the irregularity of the pulse, rate of respiration, or general symptoms during the same period. We conclude that strychnine has no effect which justifies its employment as a rapid cardiac stimulant in cases of heart failure."

Strychnine may and probably does produce an effect in the respiratory centre, but even this is only slight and uncertain. It may serve as a valuable ingredient in a tonic mixture or a laxative pill, but to rely on it in the advent of cardiac failure is futile. While strychnine has a wide and unwarranted reputation as a cardiac stimulant in Great Britain, it is largely neglected on the Continent. In Germany camphor appears to take its place, and is usually given dissolved in oil and injected into the muscles. There is, however, no convincing evidence that it is of any more value than strychnine, and it is questionable whether the cardiac power is modified by its use.

Alcohol.—Another drug which still has a great vogue as a cardiac stimulant is alcohol, more especially in cases of threatened cardiac failure, in such fevers as pneumonia and typhoid. Here, again, all the evidence is clearly and decisively against its use in such conditions, when given with the object of strengthening or stimulating the heart. It may justifiably be administered in order to induce sleep, and is a valuable ally when used for this purpose.

"but no scientific ground has been discovered for any claim made on behalf of alcohol to practical value as a direct stimulant of the heart in cases of threatened failure of the heart."

This last statement is quoted from the most recent authoritative pronouncement on the action of alcohol. Its action is mildly narcotic and sedative, and induces a comfortable feeling of *bien-être*, "a careless sense of well-being." This may be of value in the management of a cardiac patient, but does not justify its exhibition when a cardiac stimulant is indicated. I do not of course forget the transient stimulation of the heart, accompanied by some acceleration of the beat which immediately follows the swallowing of a mouthful of spirits. This is a response due to its irritant action on the mouth, throat,

and stomach, and occurs before the alcohol has been absorbed—before, therefore, it has begun to exert its specific action. This local action is of value in attacks of faintness and in the severe pain of the anginal type.

Caffeine Group.—In this we find drugs which produce a definite action on the efficiency of the cardiac systole. At the last (Oxford) meeting of the Association of British Physicians, Professor Gunn gave a demonstration of the action of drugs on the perfused heart, and the effect of caffeine was remarkable. The ventricular rate was increased, and with it the completeness of the systole. Of this group caffeine is the most commonly prescribed. Unfortunately its action on the brain sometimes prevents large doses being administered because of the resulting insomnia and palpitation. When used in pneumonia I think it is best to give it only in the morning and afternoon, and withhold it in the evening and through the night on account of its tendency to make the patient restless and sleepless. Caffeine is often prescribed in combination with a scale preparation of iron in cases of hypertension, and appears to be of service when taken for a long period. The theobromine preparations are especially useful in cases of cardiac failure where oedema has developed; their diuretic action is rapidly produced and may be of great value. The most potent is theophyllin acetate or theocin given in doses of 5 grains in a hot drink such as tea, and administered while the patient is taking digitalis. Its action is rapid and may cause diuresis even before the digitalis has had time to act. Experimental work tends to show that in addition to the diuresis the heart itself is stimulated and the coronaries dilated. This in itself would materially strengthen the heart. Unfortunately theocin is often badly tolerated, and in some patients causes nausea, vomiting, and headache. Another drug frequently prescribed is diuretin. It is better tolerated than theocin, and its action appears to be on similar lines. The dose is much larger and is 30 to 60 grains daily. Theobromine has for a long time been recommended to relieve anginal pain, and for some years I have used diuretin for this purpose. My experience certainly supports the view that the liability to anginal pain is diminished by this drug.

Adrenaline has a rapid and remarkable effect on the cardiac output, and simultaneously on the blood pressure, but its action is transitory. Some of its beneficial action on the heart is probably due to the combination of a rise in blood pressure and a dilatation of the coronaries, thereby increasing the blood supply to the heart muscle.

CONCLUSIONS.

I am afraid that as a profession we are too credulous as to the value of the majority of the so-called "cardiac tonics." The position of digitalis and its allies is of course unassailable, but their action must be fully understood if we are to obtain the best results; and their administration must not be half-hearted—the drug must be pushed to the full legitimate limit. When cardiac failure is consequent on fibrillation of the auricle, digitalis gives its dramatic results—but the sphere of its usefulness is not entirely confined to this group.

It is open to serious question whether strychnine and alcohol have any direct stimulating effect on the heart, and camphor falls into the same category.

The caffeine group, including theobromine and its compounds, has undoubtedly an influence on the heart and circulation which may be of service under certain conditions, especially when the failure is associated with oedema.

It is just as well to face the fact that we have very few drugs which can be relied upon to act as specific cardiac stimulants, and even those with an assured position only act satisfactorily in the absence of severe toxæmia.

The less we rely on "cardiac tonics" the more attention shall we give to those features in the management of the patient by which the heart can be saved from strain; the more shall we attempt to delay cardiac failure in the acute infections by dealing directly with the toxæmia; and the more shall we make every effort to maintain the quality of the blood at a high level in chronic valvular disease and thus supply the heart with an adequate blood stream.

In treating cardiac failure I would urge that the discussion of the particular cardiac tonic to be administered should come last and not first, and that certain other lines of attack should receive full consideration. It is of primary importance to diminish the number of beats. Physical rest and freedom from excitement and worry will do this. At the same time there are many patients suffering from valvular disease and other forms of cardiac disability whose reserve power can be

immensely improved by exercise, and to increase the reserve power is to diminish the liability to cardiac failure.

Hearts, like individuals, soon get "out of order," and the habit of rigidly restricting the amount of effort and exercise for no better reason than the existence of a murmur is to induce with certainty a condition of diminished reserve power. The symptoms of distress in such patients are not the result of the disease, but of the treatment. To make matters worse, many of these unfortunates become introspective and apprehensive about themselves; their outlook on life is altered, and they deny themselves all reasonable exercise for fear of straining their hearts or of inviting a sudden death.

Serious attempts must be made to give these neuropaths more confidence in their powers. For such dancing is an excellent form of exercise, and is being largely employed in America. Most people enjoy it; the periods of actual dancing are short, the exercise is intermittent, and the degree of physical effort is small. It is difficult to overestimate the value of the delight in the dancing itself as a form of mental therapy.

Exercise accompanied by enjoyment is of far more value than specified active or passive movements according to timetable, though it is obvious that the latter can be more carefully graded. There are many occasions in the more severe degrees of cardiac failure where treatment of this kind is valuable, but as a general rule exercise should be a joyful performance if the maximum benefit is to be obtained. The inclinations of the patients must be considered, and the opportunities presenting themselves will in any particular case enable a pleasant and appropriate scheme of recreation to be drawn up.

Anything interfering with the freedom of the respiratory movements must be remedied. Especially is this so in cases of pneumonia, when so much depends on a free excursion of the diaphragm; abdominal distension must be dealt with drastically. In non-febrile cases a hydrothorax must be looked for and paracentesis carried out if required.

Then sleep is essential, and I think it is difficult to over-estimate the great value of opium in the severe degrees of cardiac distress, and of the hypnotics such as the bromides and chloral and chloralaminid in the milder manifestations. We must not forget that the "foster-nurse of Nature is repose."

The vigour of the myocardium can only be maintained when the blood supply through the coronaries is ample and of good quality. Hence the optimum blood pressure must be maintained even if it be relatively high.

The soundest treatment of all for many patients is the prolonged administration of leucatinics. There is no better cardiac tonic to those suffering from valvular disease of the heart or chronic renal disease with arterio-sclerosis than a liberal supply of first-class blood to the failing myocardium.

MEDITERRANEAN OR UNDULANT FEVER.*

BY

SURGEON REAR-ADMIRAL SIR P. W. BASSETT-SMITH,
K.C.B., R.N.(RET.), F.R.C.P.

WHEN in 1900 I first went to the Royal Naval Hospital at Haslar attention in the navy was generally focused on the so-called Malta fever. My wards were full of it and remained so for six years. Since then it has always appealed to me, and I have had the opportunity of studying it in its varying forms from both clinical and laboratory standpoints for over twenty years. Happily it is now very rare in the service.

Historically it was first recognized by Marston during the Crimean war, and it was with difficulty differentiated from enteric fever. In 1886 Bruce isolated the infecting organism, which was called *M. melitensis*, as the disease was believed to be limited more or less to the island of Malta. I would here urge that the geographical names, "Malta," "Mediterranean," and "Rock" fever, etc., be dropped and the term "undulant," which describes one of the chief characteristics, be used. This was introduced by Hughes in his valuable monograph, for the disease is so world-wide that the name

* A lecture given at the West London Post-graduate School, June 22nd, 1922.

"Malta fever" for it is almost as misleading as the term "Oriental sore" for a condition found in South America.

Undoubtedly one of the most important endemic centres was Malta, for the source of infection was abundant, and the presence of a constant supply of non-immune men was provided by the changing naval and military forces, and the hospitals were hotbeds of the disease. The fever frequently developed there in patients suffering from other diseases, such as typhoid, or even surgical affections. No wonder, therefore, that as a nation we were interested in the discovery of the cause which annually gave rise to such a high amount of invaliding from the station and so many days' sickness among the fighting forces, and in the methods of prevention.

GEOGRAPHICAL DISTRIBUTION.

We now know that the fever is widely spread all around the Mediterranean littoral—in Spain, France, Italy, Greece, the Levant, Egypt, Tripoli, Tunis, Algeria, and most of the islands. During the past few years its introduction to districts far from the sea has been shown in Spain, Portugal, and France. This is a most important etiological factor. Leaving the Mediterranean, endemic centres are found at Sualdim, Aden, and India, especially in the Punjab, in China, in the Yang-tso valley, and Craig has reported it from the Philippines. In tropical Africa it is found in the Soudan, by the Blue Nile, in Northern Nigeria, and in Uganda. After the Boer war it became prevalent in South Africa, in the Transvaal and Orange River Colony—that is, when the cattle were few and more goat's milk was used. In America there appears to be a true endemic centre in Texas extending to New Mexico, and cases have been described from Peru; so you see the term "Mediterranean or Malta fever" is greatly misleading.

It was not until after the institution of the Royal Society's Commission, under Sir David Bruce, which had been working for two years and gave its final report in 1906, that the usual source of the infection was traced to the milk of the native goats, which animals appeared to be perfectly healthy at the time, though passing out enormous quantities of the infecting organisms in their milk. From these investigations, which led to the compulsory sterilization of all fresh milk used in the services or the employment of condensed milk, the disease was practically abolished and an enormous saving of money, time, and distress was brought about. No modern scientific preventive work has been more successful or of greater use to humanity. I should like to quote some words of Professor Zammit on this point:

"Before 1905 few of the employees of the Electric Telegraph Company, dockyards, etc., or their families escaped infection, but it is now exceptional for a foreign resident, who takes the necessary precautions, to be infected by the milk of a goat. The bulk of the herd that they knew better, and have not given by their sanitary officers of the danger of using unboiled milk, with the result that there has been hardly any decrease among them of the number of cases of undulant fever."

About 5 per cent. of the goats are still infected, which is a dangerous number, as a single goat may infect hundreds of persons. The attempt to limit the disease by educating the people has been a failure, so that the only prophylactic measure applicable is the destruction of all infected animals. This statement applies also to most other areas where natives have to be dealt with. Zammit also says that a goat once infected never recovers, the organism being always found in its organs, and an infected goat, apparently healthy, will, after kidding, always pass out infected milk.

The disease is seen to be mostly subtropical in distribution, and wherever it occurs endemically goats in herds are practically always present, and although the Maltese goat, which has been widely exported on account of its good milking value, is the most frequent offender, yet any goats are susceptible of infection, and from them it may spread to other animals—cows, mules, horses, dogs, and man.

Mode of Infection.

A very interesting account of the method of infection is given by Léger.

When the goats from the hills in Corsica are brought down to the towns many of the women who milk them become infected through the hands by the *M. melitensis* in the milk. The women rarely or never drink the milk. This milk is afterwards converted into fresh cheese, so commonly used in these areas, which itself is also a source of human infection, and more particularly so as the vendors often bathe the cheese in fresh milk to improve its appearance. In pasture one infected goat may infect healthy herds when introduced among them, and these may infect the

dogs and goatmen. In Spain and France the same thing occurs. Though the ingestion of the milk is the most common source of infection, the products of the milk, such as cheese and ice-creams, are dangerous.

I have mentioned how the organism may be directly inoculated through abrasions of the skin, and Séjournant goes as far as to say that, though in towns the usual source of infection is by drinking the contaminated milk, in the rural districts it is mostly caused by a local infection or inoculation of infected milk or soil. The fact that the organism is passed out of the body by the urine and faeces should make us look upon all cases as potentially infective, which necessitates the disinfection of all excreta, etc., and warning the nurses accordingly.

The specific organism is the *M. melitensis*, which, as described by Bruce, is a minute coccus or coccus-bacillus about 0.3 μ in diameter. It is, in old cultures, very pleomorphic, and is described by American authors as a bacterium, and is closely allied to the organism which causes abortion in cattle, morphologically, serologically, and tinctorially, a definite group being formed called "Brucella." The exact relationship of the two has not yet been definitely ascertained, but the latest experiments show that the abortion organism is very common in cattle and is very infective, that specific *melitensis* serum agglutinates it to a high titre, and that the pathological lesions and symptoms produced are very similar to those found in undulant fever, but its infectivity is extraordinarily slight as compared with that of *M. melitensis*, and if it is a variety of the latter it is one of very low virulence. In the group we have various strains of *M. melitensis*, the *M. para-melitensis*, and the *B. abortus*. I have found that the serum of acute cases of undulant fever agglutinates the *melitensis* and *abortus* strains about equally, but the *para-melitensis* to a much lower titre. The occurrence of cow's milk in England containing agglutinin for the *melitensis* organism is thus explained, and the absence of undulant fever caused by this milk in this country. At Greenwich I found quite a large percentage of cow's milk gave positive reactions.

CLINICAL FEATURES.

Naturally infected the incubation period is about fourteen days, but by laboratory infection it may be as short as six days (as in my own case). Here I would like to emphasize the importance of using the utmost care in the laboratory when working with this organism, and there have been so many accidental inoculations that it may be looked upon as one of the most dangerous to handle. Very often there is a long period before the onset of the disease, cases developing after leaving the endemic area. I have records of many definite cases who remained quite well while in the Mediterranean, but developed the acute disease after arriving in England.

The disease may last from two weeks to two years; the average period of 552 cases was four months. The mortality varies from 2 to 6 per cent., or rather higher in children, but from late experience it would appear that after 40 the prognosis as to life is considerably less good than in young adult age.

Four Types.

Four types may be described.

1. Ambulant—namely, those who have no symptoms but who are passing out the organism in the urine. These cases were first described by Shaw from among dockyard labourers at Malta. active sources of infection. about fourteen days, often mistaken for common fever, but there is no relapse.
2. The ordinary or undulant type of greater or less severity.
3. The malignant type, where early hyperpyrexia and intense toxæmia occur, and a fatal issue is usual. These cases are, fortunately, very rare.

A form with a hectic, intermittent type of temperature was described by Hughes; this is, I believe, only the termination of the ordinary undulant form, but being associated with cough, sweats, and general wasting, it was often called Mediterranean phthisis, but the physical signs, nummular sputum, and tubercle bacilli in the sputum are absent. These cases may last for months, and they appear to be common in South Africa. Strachan remarks how difficult they are to diagnose, especially if the temperature is only taken in the morning, when they are often entirely missed.

General Symptoms.

In an ordinary case, after a period of malaise, with headache, loss of appetite, and disinclination for work, the temperature fairly quickly runs up to 103° or more. The high fever may be continuous, but generally there is a marked fall in the morning. Slight shivers are common but rigors are rarely noticed. The tongue is moist and thickly coated, the fauces often congested; gastric symptoms may be present with vomiting and irregular diarrhoea, the stools being offensive and bilious. Frequently constipation is present from the first. The headache is severe and frontal in character and

there are sleeplessness and mental irritability. Tenderness over the spleen is generally found, and both this and the liver will be slightly enlarged. If the fever continues high a typhoid condition is produced; the tongue becomes dry and cracked, small and pointed; nervous prostration is marked with muttering delirium, or there may be drowsiness passing into stupor; the pulse gets small, rapid, and intermittent, and is markedly dirotic, and secondary pneumonia or heart failure may carry the patient off. Most commonly there are marked waves of remittent fever of varying length and intensity, separated from one another by periods of temporary absence of symptoms.

As a rule the temperature gradually rises, remitting every morning; after a short time the lassitude and debility increase, the general condition rapidly deteriorates, opistaxis is common, sweats are profuse and occasionally petechiae are found, and insomnia becomes more marked. The primary wave may last from ten days to six weeks, when improvement commences and the temperature falls to normal, or nearly so, but within a few days a relapse occurs. The symptoms of this are very similar to those of the first attack but perhaps less severe; constipation becomes more marked, the spleen and liver are more enlarged and tender, anaemia becomes more pronounced, the sweats are more profuse and distressing, and neuritis tends to appear. Each wave of temperature lasts about a fortnight, and these typically get shorter and less marked at each recurrence, but, after each wave, depression and loss of flesh increase, with the occurrence of neuritis, swollen and painful joints, and, rarely, orchitis. As the patient becomes more and more emaciated and prostrated he is subject to bronchitis, cardiac palpitations, and increased rheumatic-like pains, the hair falls out or turns grey, and the patient ages remarkably. The duration of the attack is about four months, and complete convalescence is slow.

As the disease is due to a general *melitensis* septicaemia, as the organism produces both exotoxins and endotoxins, its effects are very widespread. In some cases there are localized and cold abscesses, or areas of local necrosis are found without true formation of pus—at least, only the *M. melitensis* is found. In other cases which have run a long course the evidence of toxic infection is found in the organs, as shown by hypertrophic fibrosis of the liver and spleen with often a small-celled infiltration, or the kidney may show parenchymatous degenerations with haemorrhagic infiltration. Clinically the evidence of the toxin is shown by the pronounced insomnia, headache, backache, shifting pains in the limbs in the early stages, and later by the repeated attacks of neuralgia. Sometimes there is partial paralysis of groups of muscles which is not permanent, but I had one case which went on to complete paraplegia. The pains often alternate in intensity with the amount of the pyrexia; when the pains are severe the patient may be completely helpless, and intense hyperaesthesia of the feet may increase the discomfort. I have recently had a case which in the third month developed acute herpes, affecting the fourth and fifth lumbar nerve ganglia. The tachycardia, bradycardia, and palpitations are also of toxic origin. Cristina and Maggiore state that in young children the nervous system appears to be particularly affected by the toxin which causes meningitis and encephalitis. Deafness and loss of memory are transient symptoms. Lafont has drawn attention to the influence of the disease on pregnant women. Abortion and premature labour are favoured, particularly during periods of high fever, and he states that the infection can pass through the placenta. This is specially interesting in relation to the close analogy of the organism with *B. abortus* of cattle. The action of the toxin on the mammary gland is important, for the milk is found to be infected with the *M. melitensis*, and after a few days dries up, and a mastitis is often produced.

Para-melitensis Infection.

I have had four cases of *para-melitensis* infection—two males and two females.

The first was a lady who contracted the disease at Hyères, on the Riviera. The course of the fever was irregular intervals, and was associated, and constipation, also severe neuritis. As the disease had lasted many months I found that it was a true *para-melitensis* infection, and the patient was treated with *para-melitensis* vaccine for several months, making a perfect recovery from a state of great misery.

The second case was that of an old gentleman, aged 70, from the south of France. His condition was so severe that I did not recommend vaccine treatment. The patient died, and at the post-mortem examination a secondary streptococcal infection was found with infarcts in the spleen.

The third case was in my ward at the Dreadnought Hospital. The fever was contracted at one of the ports in the Adriatic, and he was practically convalescent when admitted, but the blood agglutinated to 1 in 2,000 with *M. para-melitensis* and 1 in 200 with *M. melitensis*.

The fourth, a fatal case, was that of an old lady who contracted the disease at Dax in the south of France. She had suffered from irregular fever for months, was greatly debilitated, and had also endocardial lesions. Vaccine treatment was used, but each injection produced marked local and general reaction, and an intense purpura followed and evidence of nephritis. The vaccine when tested was sterile and when inoculated into guinea-pigs caused no ill effects.

The reaction, therefore, seems to have been due to a definitely lowered resistance to the small amount of antigen introduced. Florintini states that the *melitensis* organism produces a toxin which acts as a haemolysin. In my last case a purpuric rash also occurred with each wave of fever; this is a serious symptom. In guinea-pigs inoculated with the two organisms cross agglutinins are produced, but the curves run more parallel with the *para-melitensis* infections than with the *melitensis*.

DIAGNOSIS.

Clinically this is often most difficult, and a great majority of the cases have been at first treated with quinine. In mild cases a diagnosis of paratyphoid is often made; in others typhoid; in others with rheumatic-like pains and swollen joints, rheumatic fever; chronic cases with much anaemia, a hectic temperature, and cough, as phthisis; and frequently pyogenic infections are mistaken. Laboratory methods alone will clear up the diagnosis.

Haemoculture.—The organism is generally not found in periods of apyrexia or late in the disease, unless in an acute relapse. Spleen puncture is rarely justifiable. The organism is, however, generally present in the articular affections, and Burcet was able to demonstrate the *M. melitensis* from the joints of infected guinea-pigs in ten out of twelve tests. From so-called cold abscesses and chondro-epiphyseal swellings the infecting organism is the *M. melitensis* and not *S. pyogenes*. A considerable quantity of blood should be removed and mixed with nutrient broth, 5 to 150 c.cm., and subinoculated daily. Sometimes it may be recovered from the washed clot by Tizzoni's method. Agglutination with due precautions will give trustworthy results, but the emulsions must be made from reliable strains; it is wise to put up with both heated and unheated serum. Several dilutions should be employed—1 in 40, 1 in 100, 1 in 400—so as to eliminate paradoxical reactions, and always a control of normal serum and specific serum should be made at the same time. It must, however, be remembered that in chronic evanescent cases the titre of agglutination may be very low or even absent, though in acute ones it usually runs very high, 1 in 1,000 to 1 in 10,000.

Isolation from the Urine.—This when positive is conclusive, but the organism is only intermittently present in the urine, so as a diagnostic method it is not of much value.

Complement fixation and precipitation tests are also specific.

I have not been convinced of the value, as a diagnostic sign, of the statement that the highest temperature tends to be early in the afternoon rather than from 6 to 10 p.m. The possibility of *para-melitensis* infections must be remembered and the appropriate organism used for the test. The blood picture will often give assistance, for in undulant fever there is a relative decrease in polymorphs and an increase in lymphocytes, so differing from that seen in pyogenic infection.

PROGNOSIS.

The prognosis for life is generally good as the mortality is low—2 to 6 per cent.—but recent research has shown that in young children, in Italy especially, it may be much higher, and after the age of 40 at home it would seem that, probably through lowered resistance, death from secondary infections is far from uncommon. It is never wise to make a prognosis for the duration of the disease, but with a period of ten days free from fever, with a clean tongue and normal pulse, convalescence may be expected. If the fever has lasted two months and profound blood changes have been set up then the disease may drag on for an indefinite time, with irregular attacks of pyrexia, painful neuritis, and general debility.

TREATMENT.

Every case should be looked upon as potentially infective, and the same care be taken as in a case of typhoid fever, warning the nurses accordingly. General good nursing is essential, and as the disease tends to run such a long course everything must be done to maintain the strength of the patient by giving as much food as he can assimilate. Alcohol should be held in reserve, so as to be of most use when myocardial signs have become marked. In the late cachectic stages stimulants are generally advantageous together with

food. The temperature should be kept, if possible, below the 103° line by cold sponging, or, if hypopyrexial, by the wet pack, care being taken to give a stimulant if necessary. Sweats should not be shortened. A continued type of temperature shows a high degree of toxæmia or the presence of probable pulmonary complication. Arthritis should be treated with belladonna or opium applications, and the neuritis by mild hypnotics, such as sulphonal, trional, or paraldehyde; a patient should never be allowed to pass sleepless nights. If the pain is very acute morphine must be given, but should be avoided if possible.

Drugs.—These are of very little use. Quinine, camphor, methyl-blue, collargol, and electrargol have given some satisfactory results lately when administered intravenously. Piazza's phenol-lipoid N is recommended—1 c.c.m. of a 10 per cent. solution in oil given subcutaneously for an average of eight days was able to cure guinea-pigs which had received lethal doses of *M. melitensis*. It is antitoxic and bactericidal. Burney Yeo's mixture was useful. Digitalis, strychnine, and stimulants, as required by symptoms, must be given.

Serums.—Donzello and Trambusti had a nucleo-protein serum, and lately Nègre and Sergent have prepared a polyvalent serum which has given good results.

Vaccine Treatment.

The great majority of workers, English and foreign, agree that vaccine treatment is the most essential factor in the treatment of undulant fever, and should be continued until the patient is immunized. With this I agree, with the following reservation: that we should not give vaccine when, in very acute conditions, the patient is already over-dosed with antigenous toxins; the ideal is a combination of an antitoxic serum and an antigenous vaccine, as the organism gives rise to so much toxin and remains alive for so long in the tissues. Burnet has shown that, when absent from the blood and urine in infected animals, the *M. melitensis* can always be demonstrated in the marrow of the long bones. Therefore always combine with vaccine treatment the administration of yeast or some other preparation to increase the phagocytic activity of the blood.

THE ANAESTHETIZATION OF PATIENTS FOR THE CLASSICAL CAESAREAN SECTION.*

BY

HERBERT R. SPENCER, M.D., B.S., F.R.C.P.,
OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

CAESAREAN section has a special interest for anaesthetists and obstetricians from the fact that the welfare and life of two or more individuals are involved.

On the obstetrical indications for the operation I will say nothing on this occasion except that they are being extended too widely by many practitioners.

On the anaesthetic aspect it requires some courage for an obstetrician to speak before an audience of specialists in anaesthetics, and my courage might have failed me had I not been convinced by an experience of thirty-five years of the value and harmlessness to mother and child of small quantities of chloroform given *à la reine* to mitigate the pains of labour, while insisting on the necessity of anaesthetization by an expert anaesthetist whenever an operation is required.

Perhaps I may claim a little indulgence for having broken a lance in behalf of your specialty at the Centenary of Ovariectomy meeting of the American Gynecological Society at New York in 1909, on which occasion, in a discussion on anaesthesia,¹ I expressed my amazement at finding that American patients were anaesthetized by nurses instead of specially qualified medical practitioners. My criticism was well received by my American colleagues; but Dr. Clarence Webster of Chicago (formerly of Edinburgh) was so affected by my accurate description of the position of anaesthetists in London that he informed the meeting that Scotland was the most important part of the United Kingdom, that in 1896 there was only one paid anaesthetist in Edinburgh, and that patients were generally anaesthetized there by medical students.

In this communication it is to be understood that the anaesthetic is to be administered by specially trained qualified medical practitioners.

* Read at a meeting of the Section of Anaesthetics, Royal Society of Medicine, November 5th, 1922. (See also p. 925.)

Of the two chief methods of anaesthetizing a patient the inhalation methods are generally preferable in cases of Caesarean section. Spinal anaesthesia is undoubtedly more dangerous than inhalation anaesthesia and has drawbacks from which the latter is free. Infiltration anaesthesia has advantages, particularly in patients with pulmonary or cardiac affections. I used it successfully twenty-two years ago² in Caesarean section repeated for the third time. But I have not employed it since.

Spinal anaesthesia and infiltration anaesthesia are less humane than inhalation methods, which induce complete loss of consciousness; and, although they are useful in certain conditions, they are not advisable as a routine method, which it is the object of this short communication to advocate.

Of the two chief inhalation anaesthetics, chloroform and ether, I suppose no anaesthetist will assert that chloroform is as safe as ether, when administered to the surgical degree for long periods, especially to pregnant women. It has therefore largely been given up in favour of ether administered either by the "open" or "closed" method.

Ether Asphyxia of the Infant.

The great disadvantage of ether is that it leads to asphyxia of the infant, which is not the case with chloroform administered to the minimal surgical degree. In my early days of performing Caesarean section I had ether administered—of course by skilled anaesthetists—but found that the child was often asphyxiated, and that hot and cold baths, stimulants, and assistants were required to start respiration in the infant. The occurrence of asphyxia in the child is still common in the practice of many obstetricians. Dr. Hubert Roberts has pointed out its fairly constant occurrence. For many years I have used the method about to be described and can assert that the Caesarean child has never been asphyxiated by the anaesthetic thus administered.

The Method Employed.

No preliminary hypodermic injection is given. The patient, prepared for operation, is placed in the recumbent posture on the operating table in the theatre and the anaesthetic is administered there. Operator and assistants are prepared and the towels adjusted.

Chloroform is then administered by the anaesthetist, who informs the operator when the patient is ready. The operation is then rapidly performed and the child, usually delivered within thirty or forty seconds from the commencement of the incision, always breathes and cries at once.

Ether is then administered for the rest of the operation, usually by the open method.

If there is any unusual loss of blood a hypodermic injection of pituitrin is given.

The result of this method of administration is that in all cases in which the classical Caesarean section is done before or soon after the onset of labour the child is born free from asphyxia and cries at once.

I think it is the ideal method of administration; but I am anxious to have the opinion of members of the Section upon this point: Does the mother run any appreciable risk in having the operation performed while under chloroform administered by an expert anaesthetist? I think she does not, having particularly in mind the tolerance of parturient women for small doses of chloroform.

THE Pelves OF RICKETY CHILDREN AS THE PRECURSORS OF THE RICKETY FLAT Pelves OF WOMEN.

BY

HUGH T. ASHBY, B.A., M.D.CAMB., M.R.C.P.LOND.,
VISITING PHYSICIAN TO THE MANCHESTER CHILDREN'S HOSPITAL AND TO THE SALTORD ROYAL HOSPITAL.

It would appear that during the last few years a larger number of women have suffered difficulty at childbirth on account of small pelves, and a larger number of Caesarean sections have been done in lying-in hospitals, than before. This difficulty is accounted for almost entirely by the rickety flat pelves so common in women who have had rickets in childhood. Hitherto little has been written about the normal or the rickety abnormal pelves of children. In order to find

out when the rickety flat pelvis starts I have made a large number of measurements of the pelvis of normal children and compared them with the measurements of pelvis of children with rickets. The pelvis of a child with rickets shows little outward signs of any abnormal measurements. In all nearly 150 pelvis of normal healthy children of all ages from 1 to 14 years have been examined and the results tabulated.

With callipers as ordinarily used in midwifery the distances were measured between (1) the anterior superior spines of the iliac crest, (2) the iliac crests, (3) the trochanters, and (4) the external conjugate diameter. These measurements are easily made; they show that the pelvis of a normal child slowly and regularly increases in size.

The pelvis of over 150 female children with rickets, at all ages from 1 to 14 years, were measured in the same way. On comparing the normal pelvis with the rickety some very marked differences were apparent, the most noticeable being the relative smallness of the external conjugate in rickets. This difference becomes more marked as the children grow older; thus at the age of 5 years the external conjugate in normal children averaged 4.8 inches, and in rickety children of the same age only 4.1 inches. At the age of 13 years the external conjugate was 6 inches in normal children and only 4.9 inches in rickety children—a difference of over an inch.

Table giving the Measurements of Normal and Rickety Pelvis of Children aged 1 to 14 years.

Age in Years.	Normal.				Rickety.			
	I.S.	I.C.	E.C.	Tr.	I.S.	I.C.	E.C.	Tr.
1 to 2 ...	5.4	5.6	3.8	6.0	4.8	5.2	3.4	5.9
2 to 3 ...	5.8	6.0	3.8	6.3	5.2	5.5	3.4	6.1
3 to 4 ...	5.8	6.1	4.0	6.9	5.3	5.9	3.5	6.5
4 to 5 ...	6.0	6.5	4.0	7.0	5.8	6.2	3.8	6.6
5 to 6 ...	7.0	7.5	4.8	7.9	6.0	6.5	4.1	7.2
6 to 7 ...	7.0	7.5	4.85	8.0	6.2	6.7	4.1	7.15
7 to 8 ...	7.1	7.8	5.1	8.0	7.0	7.5	4.8	8.2
8 to 9 ...	7.1	7.6	5.4	8.0	6.6	7.0	4.6	7.4
9 to 10 ...	7.25	7.5	5.5	8.15	7.75	8.5	5.0	8.5
10 to 11 ...	7.75	8.25	5.75	8.75	7.8	8.8	5.0	9.3
11 to 12 ...	7.75	8.25	5.75	8.75	7.8	8.5	5.0	8.9
12 to 13 ...	8.0	8.5	6.0	9.0	7.8	8.0	4.9	9.1
13 to 14 ...	8.5	9.0	6.5	9.6	8.2	8.2	5.4	9.5

I.S. = Measurement between the iliac spine. I.C. = Measurement between the iliac crests. E.C. = External conjugate. Tr. = Measurement between the trochanters.

This diminution of the external conjugate is the marked feature of the rickety flat pelvis of women and the cause of so much difficulty at childbirth. The pelvis, including the sacrum and iliac bones, like the other bones, are softened in rickets and liable to bend under strain. The chief cause of the diminished external conjugate is that the sacrum is bent and displaced forwards by the body weight. The promontory of the sacrum is carried in this way nearer the symphysis. The smallness of the external conjugate in older children shows this clearly, for it is relatively much smaller than at the earlier ages. As the child grows older and heavier the weight pushes the sacrum downwards and forwards towards the symphysis. This diminution of the external conjugate even in early life proves that it is the rickets of early childhood which is the origin of the typical flat pelvis of women.

The other measurements, interspinous and intercostal, are not markedly less in rickets than in the normal. After the age of about 9 years the interspinous measurement becomes slightly larger in rickets than in the normal. This is to be explained by the fact that the body weight presses out the iliac crests, so that the iliac fossae look forwards instead of forwards and inwards.

In the rickety flat pelvis of adults the measurement between the spines approximates closely to that between the crests, owing to the pressing outwards of the spines by the body weight. This is not so in children until near puberty, when the body weight increases so much. The measurement between the trochanters is greater in rickets than in normal

children, especially after the age of 7 years. This is no doubt due for the most part to coxa vara—a common condition in rickets—but partly to the thickened great trochanter. The average height of the rickety children measured was less than the normal height for age, owing to their lack of development, lordosis, and the curvature of the legs.

The conclusion to be drawn from these measurements is that rickets in early childhood, and continuing during childhood, is the cause of the rickety flat pelvis of adult women, and as long as rickets remains prevalent so will there be difficulty and danger with childbirth in a number of women, especially among the populations of large towns.

At present rickets shows little diminution, and the large amount which occurred during the war and since will continue to leave its mark in future years, when these children get married. It is to be hoped that the large amount of work which is being carried out all over the country on the cause and treatment of rickets will diminish its frequency in the future.

I am much indebted to Dr. J. W. Bride for his help and co-operation in this short article.

AN OUTBREAK OF DIPHTHERIA DUE TO INFECTED MILK.

BY

A. E. PORTER, M.D., D.P.H.,

MEDICAL OFFICER OF HEALTH FOR THE BOROUGH AND RURAL DISTRICT OF REIGATE.

MILK-BORNE epidemics of infectious diseases are seldom without points of interest, and a small outbreak of diphtheria, which occurred in the borough of Reigate during December, 1921, and January, 1922, was no exception.

Diphtheria had been somewhat unusually prevalent during 1921, sixty-five cases being notified in a population of slightly under 29,000. Only nine of the patients were above the age of 15; most of them were members of working-class families, and, apart from two small groups, where school infection was prominent, the cases occurred at appreciable intervals, with no obvious connexion one with another.

Between January 4th and 17th, 1922, however, I received notifications of fourteen cases of diphtheria, occurring in thirteen different houses, scattered over various parts of the borough (which has an area of 6,000 acres), every house being supplied with milk from one retailer; there was no other factor in common. Eight of the patients were adults, and nine of the houses were large residences, while two of the patients living in cottages were daily maids in large houses supplied by the same retailer. The attacks among the fourteen patients ranged from December 22nd, 1921, to January 14th, 1922. Six of the fourteen patients were males.

Five individuals were attacked on January 4th, three on January 6th, two on January 7th, and one each on December 22nd and January 1st, 8th, and 14th. A further case, a boy of 6, who was attacked on December 25th and notified on December 27th, also had milk from the same retailer.

Inquiries at the houses showed that all the patients consumed the milk as delivered, though in some of the larger residences milk intended for the children was boiled as a matter of routine. None of these children were attacked.

During January four further cases of diphtheria occurred; one of these, consuming milk from the suspected retailer, was infected whilst in London; the remainder were supplied from other sources. Among the cases notified earlier in December and those notified after January 17th there was no reason for attaching suspicion to any milk supply. This particular outbreak may therefore be considered to include fifteen cases in fourteen different dwellings.

I began to suspect that milk was the source of infection about January 9th, and on January 10th I wrote to all the general practitioners suggesting that as opportunity offered they should recommend their patients to boil all milk delivered, and I issued a letter in the local weekly newspaper on January 13th advocating the same precaution. From a purely scientific point of view this may have been regrettable, but the measure was justified by subsequent occurrences.

The implicated retailer sends out about 450 gallons a day, and supplies some 2,100 houses. The milk is derived from thirteen different farms, situated in Surrey, Sussex, and Kent,

Milk from each farm is distributed so far as is practicable to one particular round, and it was possible, therefore, to ascertain the farm from which all but one of the infected houses obtained milk. I fully expected that one farm would be implicated especially; but this was not the case, since no less than five different farms were concerned. If these are indicated by the letters A, B, C, D, and E, A supplied three houses, B one, C three, D three, and E three, whilst the fourteenth house had milk occasionally from A, occasionally from C, and occasionally from D.

Each round had a different roundsman, and infection during delivery appeared, therefore, to be out of the question. Infection at the receiving station seemed a possible solution. On inquiry I found that, as the farm churns arrived, the milk was emptied into a measuring drum, cooled (if this had not been effected at the farm), and passed through a strainer into the roundsmen's churns, the strainers consisting of four thicknesses of muslin over a metal frame. All churns and other utensils were thoroughly sterilized by steam after use. Only two men handled the milk at the dépôt. On January 11th I took swabs from the throats and noses of both, and obtained negative bacteriological results. Neither of them had recently suffered from any kind of illness, they had no families, and there had been no illness in their homes.

It is obvious, however, that if the milk from one of the farms were infected, the muslin strainer would be likely to retain some of the bacilli, which might readily infect milk from other farms when passed through the strainer subsequently, and this appeared to be the most likely solution of the problem, since it is almost inconceivable that five farms should be infected simultaneously.

Farms A, C, and D are situated in Roigate rural district, B in an adjoining rural district, and E in Kent. Inquiries at these farms yielded no information of illness resembling diphtheria among the farm hands or their families. Farms C and D are situated in a parish where there had been an outbreak of diphtheria, comprising fifteen cases in thirteen families between August 29th and December 22nd, 1921, with four further carriers in infected houses. It had been an unusually troublesome outbreak to deal with, owing principally to a concurrent epidemic of influenza, and to the omission to obtain medical advice in several instances. Although I had succeeded in identifying several "missed" cases, as well as a number of healthy carriers, I could not satisfy myself that all important sources of infection had been detected, and was left with the impression that further unrecognized attacks had occurred, probably among adults.

Early in November a schoolboy was removed to hospital whose eldest brother was a cowman at D farm. The cowman and all the other school children were examined bacteriologically, and the cowman and one girl were found to be carriers. Both were removed to hospital on November 6th, and were not discharged until February, 1922. The only other inmate of this house concerned with the farm was the father, who was bailiff. He had nothing to do with the cows, and was not examined. On January 12th I heard that the head cowman had been laid up with rheumatic fever since December 28th, and that the bailiff was doing his work. I swabbed his throat and nose that day, and obtained negative results. Negative results were also obtained at the Lister Institute a fortnight later. No cases had occurred in the neighbourhood of C farm.

So far, therefore, there was no evidence to incriminate D farm, although it appeared to be the most likely source of the Roigate outbreak. The milk from this farm is one of the earliest to arrive at the Roigate dépôt, and therefore is one of the first to pass through the strainer. I arranged that separate strainers should be used for A, C, and D farms on January 12th, and sent these to the Lister Institute for bacteriological examination, intending to await the report before taking any further action. As the public had largely adopted my suggestion of boiling their milk, there was little risk of a spread of infection. The examination was completed on January 25th, both cultural and inoculation investigations being made; diphtheroids were isolated, but no true diphtheria bacilli were found.

The problem, however, was solved on January 22nd, when another cowman, son of the head cowman from D farm, was removed to hospital with diphtheria. His faucial attack began on January 19th, but on admission to hospital he was found to have sores on both arms which had existed for nearly six weeks. Unfortunately energetic treatment was successfully applied before I had an opportunity of making

a bacteriological examination, but I was assured that the sores had the appearance typical of diphtheritic infection of the skin. The inquiries made at each of the farms A, C, and D had included the existence or otherwise of such sores, but their presence had been denied in this instance. The farm supplied about seventy gallons a day, milking being carried out by four cowmen. In the course of the next few days I took swabs from the throats and noses of nineteen persons on the farm, including all the remaining cowmen and other farm hands and their families. Seven carriers were found, one being the head cowman, who had been laid up with rheumatic fever, as already mentioned, the remainder being children, three of them in cowmen's families. All were removed to hospital. I had the teats and udders of all the cows, thirty-three in number, examined. On the udder of one was a superficial ulcer, apparently of traumatic origin. A swab from it yielded a negative result. Another cow had a cyst in a dry quarter. All the remaining cows were healthy.

On January 23rd the milk from D farm was withdrawn from the retailer's supply, was pasteurized, and made into butter. Apart from a few gallons consumed by the families employed on the farm all the milk is sent into Roigate. It is curious that none of the children on the farm contracted diphtheria; but possibly some of the carriers were accounted for in this way.

Owing to the impossibility of confirming the nature of the sores on the young cowman's arms bacteriologically it cannot be asserted definitely that he was the actual infecting agent, though this is by far the most likely explanation. The illness which laid up his father was undoubtedly rheumatic fever, which may or may not have been associated with an attack of diphtheria; but in any case he was not engaged in milking at the time the outbreak was at its height. Although carriers were found in the family of another cowman he himself appeared to be free.

This outbreak differed from the usual textbook description in the absence of any marked suddenness in its appearance, and in the occurrence of only one instance of multiple attacks in the same household. It is also somewhat remarkable that so few cases should have occurred among the 8,000 or more consumers of the supply. This, however, may largely be accounted for by the practice of allocating the milk from each farm to a particular round.

The character of the attacks was mild. There were no deaths, but in many instances the infective period was a very long one.

THE ACTION OF CARBON TETRACHLORIDE ON THE LIVER.

BY

J. F. DOCHERTY, B.A., M.B. TORONTO,
DIRECTOR OF ANCHYLOSTOMIASIS CAMPAIGNS FOR CEYLON;

AND

E. BURGESS,
ACTING DIRECTOR OF BACTERIOLOGICAL INSTITUTE.

IN view of the report by Dr. W. G. Smillie and Dr. S. Pessoa¹ to the effect that carbon tetrachloride in small doses produced a definite fatty degeneration of the liver and kidneys of dogs it was deemed advisable, before using this drug generally in Ceylon as a vermifuge, to ascertain whether or not these lesions were produced in man, using the maximum dose of 5 c.cm. as defined by Hampton and Nicholls.² Leach³ reports from autopsy that no macroscopical change was noted in the liver or kidney following a 12 c.cm. dose; apparently no microscopical examination was made.

With the approval of the superintendent of prisons and the personal consent of the prisoners, two condemned men were treated with 5 c.cm. of carbon tetrachloride and one with 8 c.cm. in two doses of 5 and 3 c.cm. The anthelmintic was given on an empty stomach, followed by tiffin of rice at the hours mentioned, and, as indicated, No. 1 received a post-purge of 1 oz. of saturated magnesium sulphate solution three and a half hours later; No. 2 received the same eight hours after treatment; while No. 3 received none, having vomited the first and declined the second.

Autopsies were performed on dates mentioned, when the entire intestinal tract from the pylorus to, but not including, the rectum was removed after being double ligatured in

order to keep the contents for examination. The liver and left kidney were removed in each case and examined macroscopically and microscopically. The following is a report of the examination and findings:

	Prisoner 1.	Prisoner 2.	Prisoner 3.
Date examined ...	July 15	July 31	July 31

Pulse rate ...	—	—	None given
Purgo ...	—	—	August 19
Date of autopsy	July 22	August 15	
Examination of bowel contents:			
Anky. duod. ...	Negative	Negative	Negative
Acanth. ...	Negative	Negative	Negative
Trichuris ...	9	12	14
Oxyuris ...	Negative	17	
Liver:			
Macroscopically ...	No change evident	Slightly friable	Very friable
Microscopically ...	No well-defined change	Granular degeneration of liver cells	Fatty degeneration of liver cells
		Leucocytic infiltration	Diffuse leucocytic infiltration
Kidney:			
Macroscopically ...	No change evident	No change evident	No change evident
Microscopically ...	No change evident	No definite change	Cloudy swelling of proximal tubules

From the above it is quite evident that the anthelmintic, in the quantities mentioned, produced lesions in the liver in two cases, as Smillie anticipated; in this account it seems in advisable to prescribe even a 5 c.cm. dose with purgation, let alone without. It is apparent also that this dose as a maximum borders on the danger line. A safe maximum seems to be 3 c.cm., since it has been given to a number of patients in Ceylon without producing any feeling of discomfort, though so far no autopsy has been performed on any individual so treated to ascertain whether or not the kidney or liver was injured.

From its action as a vermifuge we agree with both Leach's¹ and Hampton and Nicholls's² report that it seems to be practically specific for ankylostomes, fairly efficient in the removal of *Ascaris lumbricoides* and *Oxyuris vermicularis*, and of little value in the elimination of *Trichuris trichiura*.

We wish to thank Mr. A. F. G. Walker, Superintendent of Prisons for Ceylon, for his assistance and the interest shown in the experiments, and Dr. S. Chelliah, M.B., C.M., assistant pathologist of the General Hospital, for his confirmation of the pathological findings.

NINETIETH ANNUAL MEETING
OF THE

British Medical Association.

Held at Glasgow, July, 1922.

PROCEEDINGS OF SECTIONS.

SECTION OF MEDICINE.

Professor T. K. Monro, M.D., F.R.F.P.S., President.

PRESIDENT'S INTRODUCTORY REMARKS.

PROFESSOR T. K. MONRO, in offering to the members of the Section a very hearty welcome to the city and to the classroom in which they met, remarked that in the regulations drawn up by the Council of the Association there was a merciful provision that the President of a Section should not deliver a presidential address. He, therefore, in a few words described the arrangements which had been made for the three days' work of the Section.

DISCUSSION ON EXOPHTHALMIC GOITRE.

OPENING PAPER

BY

GEORGE R. MURRAY, D.L., M.D., D.C.L., F.R.C.P.,

Professor of Systematic Medicine in the University of Manchester; Senior Physician to the Manchester Royal Infirmary.

IN arranging a discussion on exophthalmic goitre it is important to select certain aspects of this subject for consideration so as to elicit definite information or opinions upon them from those taking part in the discussion. Although much attention has been paid to the pathology, symptoms, and treatment of this malady, too little consideration has been given to its prevention, and it will be useful to consider what is known of its causation so as to discuss what measures can be taken to prevent the onset of the disease or to check its development in the early stages, even if this is possible in only a small number of cases. It will be advisable, in the first place, to allude to the pathology of the condition and, incidentally, to the cause of one puzzling symptom—the exophthalmos. Prevention and a few indications as to treatment will then be considered.

At the Annual Meeting of this Association in 1896 I opened a discussion¹ on the pathology of exophthalmic goitre and briefly reviewed the current views of the day, adducing evidence which led to the conclusion "that in exophthalmic goitre there is an excessive formation and absorption of thyroid secretion which may or may not be normal in character and that the symptoms of the disease are due to the presence of this excess of secretion in the blood, and to its action upon the tissues and especially upon the nerve centres in the medulla." This view of the essential nature of the malady is still generally accepted and the term "hyperthyroidism" is used to denote the various degrees of thyroidal overactivity. In a recent British Medical Association lecture² I have indicated a convenient clinical classification of the main types of hyperthyroidism, but on this occasion it is advisable to discuss only exophthalmic goitre and not the minor degrees of hyperthyroidism.

The acceptance of the view that exophthalmic goitre is due to a thyroidal toxæmia has directed attention to the importance of treating the thyroid gland, and experience has shown that when, as the result of either medical or surgical treatment or in consequence of spontaneous atrophy, the secretion is reduced to normal amounts, recovery from the malady takes place. This sequence of events appears to be a strong indication that the thyroid alone of the endocrine glands is primarily at fault in this disease. It has been suggested that one or more of the other endocrine glands may play a primary part in the production of symptoms, but no clear evidence has been brought forward to support this view. The thyroidal hormones certainly play a part in stimulating the activity of other endocrine glands, just as they increase the activity of the sweat glands, but this appears to be entirely a secondary result of a primary hyperthyroidism. The symptoms can almost all be accounted for

by a chronic thyroidal intoxication, and have been reproduced in man by giving large doses of thyroid extract. The actual causation of the exophthalmos, which is such a striking feature in many cases, is, however, still under consideration, and it is to be hoped that further information on this subject may be elicited in this discussion.

It has been held that the proptosis may be due to vascular engorgement, to muscular action, or to excess of orbital fat. As it cannot be reduced by pressure on the eyeball and persists after death, it cannot to any appreciable extent be due to venous engorgement. It has often been stated that the protrusion is due to the action of Müller's muscle, but this has always appeared to me to be a totally inadequate explanation. I have consulted my colleague Professor J. S. B. Stopford as to the anatomy and action of these muscular fibres, and he has kindly given the following information. In 1858 H. Müller described a layer of unstriped muscle bridging over the sphenomaxillary fissure and posterior part of the infraorbital canal. This muscle corresponds to a more extensively developed layer which is found in the periorbital fascia of various mammals. It is attached to the periosteum, and is innervated by the sympathetic nervous system. In his own dissections Professor Stopford has not found it possible to recognize this muscle macroscopically in the human orbit. It is only on microscopic examination of the tissue removed from the region of the sphenomaxillary fissure that a few smooth muscle fibres may be found. It is obvious that such a feeble muscle could have no power of producing proptosis against the normal action of the external ocular muscles and of the optic nerve in holding the eyeball in its proper position. In addition to this, Professor Stopford gives three reasons for concluding that it seems impossible for Müller's muscle to be responsible for exophthalmos in the human subject: (1) Müller's muscle is only composed of a few scattered fibres, and it is quite rudimentary and atrophic in man. (2) Even if this muscle had an appreciable power of contraction it is too far from the globe, and chiefly separated from it by compressible fat, to have any power to project the eye forward. (3) If it had any action on the globe it would push it obliquely upward and forward. The same arguments would, I consider, also largely apply to the fibres described by Landstrom. It is to be hoped that this inadequate explanation will disappear from our textbooks.

In almost all other forms of proptosis there is a definite mechanical cause to be found, and in exophthalmic goitre fat is certainly present in excess in the orbit in many if not in all cases. I have recorded a fatal case in which, in spite of marked general emaciation, half an ounce of fat was dissected out of one orbit. I am unable to explain why fat should accumulate in this position, and as far as I am aware no special examination of this orbital fat has yet been made to determine if it differs in either structure or chemical composition from normal fat. It seems clear that this excess of fat in the orbit is the essential cause of the proptosis in Graves's disease and accounts for its persistence in many cases after the other symptoms have subsided and the patient has practically recovered. The fat when removed during life has been found to be oedematous and slight variations in the degree of proptosis from time to time may be due to variations in this oedematous condition.

In speaking of recovery from Graves's disease it must be remembered that, although there may no longer be any hyperthyroidism, results such as exophthalmos or chronic myocarditis may persist long afterwards, just as chronic renal disease may persist after scarlet fever or chronic endocarditis after acute rheumatism. As this aftermath of exophthalmic goitre often militates against the complete success of any line of medical or surgical treatment in severe or chronic cases, it is important to examine briefly the conditions which favour or excite the development of exophthalmic goitre, as well as the conditions which aggravate mild into serious forms, or induce relapses after periods of improvement. A full discussion of these factors may supply information which will help us to prevent the onset of the disease in some cases and to avoid aggravating it, when already present, in others. In many cases no adequate cause can be ascertained, and we cannot explain why the disease has developed.

For the purpose of this discussion I have reviewed my notes on 300 cases of exophthalmic goitre, 71 of which were men and 229 women, seen in private practice during the eleven years 1911-21. This proportion indicates that women are much more prone to suffer than men. It is of interest to note

that in this series the malady occurred about three times as often in women as in men. In another series of 120 cases which I recorded² in 1903, the proportion was exactly eleven to one. This difference suggests that the disease now occurs more frequently in men than it did formerly. Be this as it may, it is evident that sex is still one important predisposing factor. In no less than 232 (77 per cent.) no other predisposing or exciting cause was found. It has long been recognized that family predisposition occurs in some cases, as a mother and daughter or two or more sisters may be affected at the same or different periods of life. Dr. Hector Mackenzie¹ found a family history of the disease in 10 per cent. of 438 hospital and private cases. This tendency was present in 26, or nearly 9 per cent., of my cases. This predisposition should be borne in mind, and any early signs of hyperthyroidism in a relation of a patient suffering from Graves's disease should be treated promptly as soon as they appear. Either sudden or prolonged nervous strain may be a precursor of the disease in some cases, but not so often as the more striking examples might lead one to expect. A sudden nervous strain, such as is caused by an accident, fright, or emotional shock, had occurred in 38 (13 per cent.) of my cases, while prolonged periods of anxiety or worry owing to either domestic or financial causes were recorded in 17 (6 per cent.) cases. Overwork was given as a cause in 11 (4 per cent.) cases, and nursing, chiefly in war hospitals, in 8 (3 per cent.). It is remarkable that exophthalmic goitre does not often follow physical injuries, as in only 9 (3 per cent.) of my cases had an accident occurred, and 7 had recently undergone an operation. In a separate series of fifteen soldiers suffering from various degrees of hyperthyroidism, who were under my care at the Manchester Royal Infirmary, not one had been wounded. In these 15 cases the symptoms had developed in 4 after the explosion of a shell or mine, in 1 after prolonged exposure to fire in the trenches, in 5 after dysentery, malaria, or tonsillitis, and in the remaining 5 after the stress of general service conditions during the war. I do not remember seeing a single case of exophthalmic goitre following a wound in a military hospital in either England, France, or Italy. It will be interesting to learn the experience of others in this respect.

The strains and accidents of life we cannot prevent, but in those who have been subjected to them we should be on the look out for early signs of hyperthyroidism, special care being exercised in the case of women who have a family history of thyroidal disease or who already have some enlargement of the thyroid gland. The occupation of teaching appears to be a predisposing factor, as 11 (4 per cent.) of my cases were school teachers. Some educational authorities now realize this, and are unwilling to accept a young woman with a goitre as a teacher owing to this liability to develop a toxic adenoma or Graves's disease in later life. If any septic focus is present naturally it must be treated, as it will tend to aggravate the symptoms, but there is little sound evidence to show that septic infection is a cause of the malady, as in my series it was present in only two cases. Of general infections influenza is notable in that it shortly preceded the onset in 18 cases. Exophthalmic goitre is a widely spread disease, and it is difficult to determine the influence of locality on its development. It is remarkable, however, that 19 of my cases came from one part of the valley of the river Goyt, which divides Cheshire from Derbyshire.

One other aspect of this subject I wish to mention, and that is the relationship of simple parenchymatous goitre to exophthalmic goitre. In a certain number of cases of simple goitre symptoms of hyperthyroidism appear and the condition is known as toxic adenoma; in a smaller number definite exophthalmic goitre appears. This occurred in 12 of my cases. The proportion of cases in which this occurs is not known, but it is sufficiently large to encourage us to make more energetic attempts to prevent or treat cases of parenchymatous goitre which are so often regarded as harmless and to be on the look-out for the earliest indication of hyperthyroidism. In a certain number of cases there is both a predisposing and an exciting cause, so that in a patient with family predisposition or a pre-existing goitre the onset of the disease follows a nervous shock or strain. Endemic goitre in some cases is due to a deficiency of iodine in the body, and it has been suggested by Professor Mellanby³ that the influence of cod-liver oil in preventing abnormal changes taking place in the thyroid gland of animals fed on a certain diet is due, in part at least, to the iodine it contains.

In America it has been found by Kimball⁴ that the administration of small doses of iodine, such as 3 grains of sodium

iodide, daily for ten consecutive school days each spring and autumn to girls during the school age has been followed by a striking diminution in the number of cases of goitre in districts where it is usually endemic. This preventive treatment should be adopted in all such regions, and it is not unreasonable to expect that by diminishing the tendency to simple goitre in early life we may also lessen the number of cases of exophthalmic goitre occurring in later life. It must be mentioned in this connexion that treatment with iodine is quite unsuitable for those who already show any signs of hyperthyroidism. In taking these precautions the importance of a pure supply of drinking water must not be forgotten, as it has long been held that contamination of the drinking water plays an important part in the production of goitre.

As much may be done to prevent the development of Graves's disease by the suitable treatment of the earliest stage of hyperthyroidism, it may be pointed out that one of the earliest symptoms of this is a constant feeling of exhaustion or weariness. If a persistent increase in the pulse rate, some loss of weight, and an increase in the basal metabolic rate are also present, with, or even without, some increase in the size of the thyroid gland, they indicate, in the absence of any obvious cause, an early hyperthyroidism even before it is recognizable by the usual clinical signs. Prompt treatment by rest, suitable diet, x rays or radium, and drugs has then its best opportunity, and may prevent further development of the malady into actual Graves's disease.

The same principles may also be applied to those who already suffer from the disease so as to save them as far as possible from preventable aggravation of their symptoms. An attack of influenza so often increases the severity of the symptoms that every possible precaution should be taken to protect patients from this infection. If influenza is contracted rest in bed must be continued until the pulse returns to its previous rate and convalescence is fully established. Neglect of this precaution may result in an aggravation of symptoms lasting for weeks or even months. When pregnancy occurs in a patient suffering from exophthalmic goitre it should be allowed to continue to its natural termination. Should a miscarriage or premature birth take place special care is required as well as a prolonged period of rest afterwards. During a normal pregnancy and during the period of lactation the symptoms are often notably diminished, but there is a marked tendency for them to flare up again just after the birth of the child or later on when it is weaned, so that great care must be exercised at both of these times. Residence at the seaside frequently aggravates the symptoms of Graves's disease, and is therefore to be avoided.

As I have so recently expressed my views on treatment elsewhere¹ they will only be briefly summarized here. As we shall have the advantage of hearing Mr. James Berry's experience of the surgical treatment of Graves's disease my remarks will be chiefly confined to medical treatment. In slight or early cases—and the importance of recognizing these may again be emphasized—medical treatment alone is required. This consists of rest, suitable diet, and radiological combined with medicinal treatment, the details of which must be adapted to the requirements of each individual. In cases of medium severity a similar course of treatment should be carried out for not less than six months. If, however, time is a matter of great consideration to the patient or the thyroid gland is much enlarged surgical treatment may be advised at once. If medical treatment has failed to bring about definite improvement by the end of six or twelve months, operation may be advised.

The chief difficulty arises in those cases in which the symptoms are severe when the patient first comes under observation, and it is desirable to reduce the hyperthyroidism as soon as possible. It is just in these cases that the risks of an operation are considerable, and I should like to know if these are lessened by a preliminary ligation of one or more thyroid arteries. As a rule this preliminary operation, which has been largely practised in America, seems to me to be unnecessary. In any case I am convinced that, if a thyroidectomy is undertaken, at least three-fourths of the goitre should be removed, otherwise improvement is only partial and patients are disappointed to find that, after accepting the risk of an operation, they are by no means free from symptoms.

DISCUSSION.

Dr. C. M. WILSON (London) said that at a discussion on exophthalmic goitre held at the Royal Society of Medicine in 1921, he had ventured to point out the disquieting similarity between that debate and one held in the same place in 1912. They were concerned not with some difficult and intricate problem of causation, but with the actual results of treatment, and yet a decade had gone by without bringing them any nearer agreement. Those who sought guidance in following a rational procedure in the treatment of exophthalmic goitre were hampered by the vague language in which results were recorded and by the fact that there were too many advocates in these discussions. They might hope that when basal metabolic measurements displaced such terms as mild, moderately severe, and severe types, so that the degree of severity of a case of Graves's disease, before and after treatment, could be expressed in figures and not in language coloured by the natural gratification of surgeon or radiologist in bringing about a cure, it would then be possible to tell exactly what type of case was being recorded and the precise result of the particular treatment instituted.

These discussions were devoted to the management of what was termed a severe, or moderately severe, case of exophthalmic goitre. What happened to such a patient when admitted to hospital? Commonly rest in bed was followed by improvement, and that improvement continued for two or three weeks. For example, if the clinical course was recorded in measurements of the basal metabolism, the figure representing the basal metabolic rate fell during that period from, for example, +55 to +30, but at the end of that time no further fall occurred. No matter how long the patient was kept in bed, the figures remained at about the same level. Three alternatives were now open to the physician: (1) he might allow the patient to be discharged from hospital better than on admission but not cured; (2) he might resort to x rays; or (3) he might call in a surgeon. Such discussions as the present one were entirely taken up with the conflicting arguments for each of these three alternatives. With regard to the first course this was a rational line to follow, if they agreed with Sir William Halo-White that exophthalmic goitre was a disease that tended, in the course of a few years, to cure itself, and that meanwhile no great harm would befall the patient or her tissues. For, if that were so, all they stood to lose by adopting conservative measures was a period of invalidism extending, perhaps, over some years; that might be for many economically impossible. But if that view was not in accordance with their clinical experience, if it remained in the field at all simply because its refutation depended on following a sufficient number of cases over several years, which was in practice exceedingly difficult, if in brief their experience was his, that a comparatively large number of patients with this disease suffered grave and permanent damage to their tissues, they would then be reluctant to allow the patient to leave hospital, better it was true, but too likely to shed the benefits conferred by hospital immediately she was submitted to the stress of everyday life. They would feel that some further attempt must be made to bring down the basal metabolic rate to normal.

To that end, since rest and the administration of drugs had done all they could do, they were compelled to call in the assistance of either the surgeon or the radiologist. It was maintained by some that surgery was both unnecessary and unsafe. Unsafe, because the mortality even in the hands of surgeons with special experience in operations on the thyroid gland was in the neighbourhood of 5 per cent.; unnecessary, because the disease tended in time to cure itself. If, however, they agreed with the view he had put forward, that exophthalmic goitre was a grave disease, and that it was the duty of a physician not to rest content till the excessive activity of the gland had been reduced to within normal limits, if they took that view, then they would not be turned aside from its logical consequences, even by a mortality as high as 5 per cent., provided always that there was no safer alternative. Did such an alternative exist? It was true that the effect of x rays was uncertain and often disappointing in the later stages of the disease, and it was also true that neither by basal metabolic measurements nor by clinical means could they say, in advance, which cases would respond to x -ray applications and which would fail to respond. Yet he would ask, Would a physician, knowing the mortality to be 5 per cent., submit, if he had Graves's disease, to an immediate operation, when there was a reasonable possibility

that the same end might be attained by the radiologist without any risk? He thought that in these circumstances he would think discretion the better part of valour, and would knowing that six months might be spent without profit in giving x rays a trial, he would, nevertheless, deliberately choose the path of safety.

The matter has been well put by Mr. Walton of the London Hospital, who had said that he never operated in the first six months of the disease. He would like to amplify that advice by saying that if an intelligent patient were in possession of all the pros and cons she would probably decide that while she would not have an operation in the first six months of the disease, she would not allow more than a year to elapse without seeking surgical assistance, if other and safer means of treatment had then failed to bring the basal metabolic rate down to normal. That appeared to him to be the sane and simple conclusion to which they were driven by all the facts. Their judgement would not be swayed by overstatement on the part of either surgeon or radiologist. Some surgeons came to these discussions contending that the desired result in that disease was more certainly and more permanently attained by operation than by any other means. That was a comparative claim. It implied that the surgeon either had personal and prolonged experience of other methods, or, in default, that he had access to published statistics with which he could compare his own results. But, as they knew, no such data existed. Without such an intimate experience of alternative measures, these surgeons' results had only the value of uncontrolled experiments. Others brought patients and photographs of patients to prove that overactivity of the thyroid gland could be controlled by operation, a point no one disputed. The immediate benefits of surgery were not in question; they were concerned rather with the permanency of such results and with the necessity for operative measures. They should not be driven by the zeal of enthusiasts to deny the benefits surgery could err in this disease when all other means had failed. Perhaps this warning was superfluous in that debate because they had the advantage of Mr. Berry's experience and cautious outlook.

But, he would ask, were they not on the wrong tack altogether in devoting these discussions to the case of severe and moderately severe cases of Graves's disease? Would it not be altogether more profitable if they could ban the mention of such phases of the disease so that they might hear something of early diagnosis and of the causation of exophthalmic goitre? In other diseases their one aim was early diagnosis, so that treatment might be instituted when it would be most effective. But if unusually favourable results were reported in the treatment of exophthalmic goitre they were met with the criticism that the cases described were not Graves's disease at all, because they lacked this or that sign of the complete classical picture, till they were led to question whether this disease had a youth at all. If they were discussing the treatment of pulmonary tuberculosis would they confine their remarks to cases with cavity formation? These discussions were frittered away in desperate attempts to patch up the damaged tissues of patients when the malady had reached a late and intractable phase, whereas they surely should be devoted to the means necessary to prevent that damage.

That brought him to basal metabolic measurements. By means of these they could follow the clinical course of a case as upon a chart, so that they learnt when rest had done all that it could do, when to operate and when not to operate, and to record their results so that they were intelligible to others. These measurements rendered diagnosis practicable at a time when it was uncertain clinically and they encouraged the physician to institute vigorous treatment when it was most fruitful in results, by assuring him that there was an overactivity of the thyroid and by convincing him that at such a stage it could be rapidly reduced to normal limits. They might even claim that these measurements alone made such early treatment possible, for without them there was a probability that the x ray applications would be continued till a condition of hypothyroidism was produced. It was quite unsafe to use x rays at such a stage of the disease without checking the treatment by measurements of the basal metabolic rate. If that warning were neglected it would not be long before the most sceptical was convinced of the potent influence of x rays over the functions of the thyroid gland. He had been impressed by the need for caution by the remarkable effect of such treatment in women suffering from so-called functional menorrhagia without any abnormal pelvic signs to account for the loss. Working with Mr.

Bourne, he had found in those patients a raised basal metabolic rate, though the thyroid was often not enlarged. X-ray applications to the thyroid were followed by speedy relief of a type of menorrhagia that had generally resisted curettage and other treatment. He thought that the circumstances in which this condition arose threw an interesting light on the difficulty of saying what was Graves's disease and what was not, and on the effect of treatment of hyperthyroidism by x rays. Along these lines they might progress to a time when the cases to which they now devoted those debates would be regarded as clinical curiosities.

Mr. JAMES BERRY (London), after thanking the committee of the Section for kindly inviting him, an operating surgeon, to take part in the debate, said that the subject was essentially one for collaboration between physicians and surgeons. He drew attention to the excellent series of specimens of exophthalmic goitre that Dr. Scott Williamson and Dr. Innes Pearso had sent to the pathological exhibition, and commented upon the solidity of the gland, the great increase in cellular elements, and the almost complete absence of colloid in all the specimens. In the short time at his disposal he thought it would be best if he limited himself to giving his own personal views on the indications for and against operation, and to the principal dangers of the operation, and the best means of avoiding them, without going into operative details.

In many respects he found himself in agreement with Professor Murray and Dr. Wilson. He did not think that early and mild cases of true exophthalmic goitre required operative treatment, since many such cases recovered spontaneously under medical treatment and rest, with or without the help of x rays. X-ray treatment should not be carried out too energetically or for too long a period, as it might easily lead to myxœdema or other complications. Advanced cases of many years' duration in which the disease had practically died out, leaving behind it exophthalmos, a fibrosed gland, and a permanently damaged and irregular heart were also unsuitable for operation. Ultra-acute cases with great mental excitement (amounting sometimes to actual mania), very rapid emaciation, and excessive muscular weakness were also not suitable, especially if electrocardiographical examination showed acute myocardial degeneration of the heart muscle. He expressed his indebtedness to Dr. Strickland Goodall, who had for many years been seeing cases of exophthalmic goitre with him. Cases of myocardial degeneration, whether early and acute, or late with much dilatation, were especially dangerous, as the patients were apt to die from sudden heart failure either before, during, or shortly after operation, or indeed without any operation. The existence of such cases would be recognized by all operators who had had much experience of exophthalmic goitre operations.

The course of Graves's disease was rarely steadily progressive. There were usually ups and downs in its course. It was not during an exacerbation, but rather during a remission in the severity of the symptoms, that operation could be undertaken with the best prospect of success. Yet it was just during a period of exacerbation that usually the patient, and sometimes the doctor, was most anxious for operation. It had been well said that an operation for exophthalmic goitre should never be looked upon as an emergency operation. In some fairly acute cases, especially those of rather large goitres, in which removal would be too dangerous, a preliminary ligation of one or both superior thyroid arteries was, in his opinion, of great value. The patient often improved so much after this small operation that a subsequent removal could often be performed with much less risk. He had not himself lost a case after ligation for more than ten years, although he had performed a large number within this period. Ligation of the inferior thyroid artery he now never performed. It was probably very nearly, if not quite, as dangerous as removal of a lobe and was certainly much less efficacious. It was his custom never to operate upon an exophthalmic goitre unless it had been at least several days under his personal observation in a nursing home. In this period fright was largely eliminated, the heart generally quietened down considerably, and the patient gained confidence. All these were valuable adjuncts to the operation. He never operated upon a frightened or unwilling patient. He always warned the patient beforehand to expect that she would probably feel ill and miserable for a day or two afterwards. Consequently they were not unduly anxious when such symptoms did appear. He had no belief in humbugging patients by not telling them what they might

reasonably expect to suffer. Most patients who were really ill with exophthalmic goitre welcomed the operation rather than shrink from it, since it afforded them a prospect of relief. It was always wrong, in his opinion, to tell patients with true exophthalmic goitre that they would be cured immediately or even quickly by the operation. That was what they only too often expected, and they were apt to be disappointed when they found this did not occur. The utmost that could truthfully be stated was that the operation of removal of part of the goitre would almost certainly be followed rapidly (generally within a very few days) by great amelioration of most of the symptoms (except the exophthalmos, and that the prospect of ultimate complete, or nearly complete, recovery was greatly enhanced.

Mr. James Berry admitted that he did not like operating upon exophthalmic goitres. He felt that one could never tell when one might meet with a sudden and unexpected death in these cases. On the other hand, he liked to operate upon suffocating innocent goitres, and the worse the dyspnoea the better he was pleased, because with these cases he knew where he was. He knew that in the vast majority of such cases he could cure them rapidly and permanently by removing the source of the dyspnoea. In the last few hundreds of operations that he had performed for the removal of innocent goitres of all degrees of severity, excluding exophthalmic and malignant cases, the mortality had been called "false" cases of what he had well under 1 per cent. With operation for the removal of true exophthalmic goitre he could not get his mortality quite down to 4 per cent., having lost 5 patients out of 116. If an operator included in his statistics (which he himself did not) cases of so called "false" exophthalmic goitre—namely, cases of encapsulated tumours, cysts, or other forms of innocent goitre with some tachycardia and tremor—as was often done, the results could be made to appear much more satisfactory. These latter cases could usually be cured quickly and permanently, and with but little risk. But such cases, whatever their pathological relation might be to true exophthalmic goitre, only served to confuse the issue if they were classified with them in operative mortality statistics.

With regard to the ultimate results of operation for removal of exophthalmic goitre he regretted that he was unable to give these for all his cases up to date, but he referred to a consecutive series of 78 cases that he had communicated to the Royal Society of Medicine last year. They included all the cases operated upon during the years 1913 to 1919 inclusive and had been reported upon in 1920 at periods varying from a few months to seven years after the operations. Of these, two-thirds (53) were found to be practically well, able to do their ordinary work, and to enjoy life, although in many cases some traces of the original disease, especially the exophthalmos and a tendency to palpitation on exertion, still remained. One quarter (18) were "much improved," while 1 was "improved," in 2 there had been no improvement, 1 was worse, and 3 had died of the operation. None of this series had been untraced. With regard to the anaesthetic, he had entirely abandoned the use of chloroform, which he thought should never be employed for exophthalmic goitre operations, nor indeed for any goitre operations. Although local anaesthesia had its advantages for some cases, he usually employed a very light open ether anaesthesia.

Dr. JAMES R. RIDDELL (Glasgow) said: The reasonableness of treating Graves's disease by x rays depends on the assumption that the disease or its increased secretory activity of the facts are established that minute dose epithelial activity, while larger doses cause inhibition and destruction of epithelium, thickening of blood vessel walls with shrinkage of the vessels and increase of the fibrous elements in the tissues. In looking over the x-ray literature one finds reports of cases treated as long ago as 1905; thus the method has had time to be well tested, and the ever-increasing numbers reported prove that it has not been found wanting. It is difficult to speak of cures in such a disease as exophthalmic goitre, and I gather from the reports that complete disappearance of symptoms is claimed only in a small percentage. All are agreed, however, in claiming very great improvement in the patients' condition in about 80 per cent. of cases. While I have not kept exact records I have formed the opinion from my own experience that the above figure is substantially correct. The general opinion is that the symptoms disappear or improve in the following order: First there is an improvement in the pulse rate and condition.

Then the sweating, tremors, and headaches become less and the weight increases. The thyroid does not always show much reduction in size, specially if it is hard and not much enlarged to begin with. Lastly the exophthalmos may subside in some cases, but often it does so only to a slight degree. I cannot say that I have myself noted any definite sequence of events.

It has been my custom to advise against x-ray treatment in those slight cases occurring in girls about puberty, on the ground that they usually get well without it, and on the general principle that the less one is exposed to x rays the better; but Dr. Russell H. Boggs of Pittsburg, in an excellent article in the *American Journal of Roentgenology*, 1919, speaks strongly in favour of x raying these cases. Regarding technique there are two methods. One may give minute doses repeated at short intervals two or three times a week, or a full dose may be given once in three or four weeks, using hard rays filtered through several millimetres of aluminium (3 or 4 mm.). The first seems to be analogous to prescribing an ordinary tonic to be taken a few drops every twenty minutes instead of the more usual tablespoonful three times a day. It is not so accurately measurable and I can see no possible gain in it. It should be borne in mind that minute doses are stimulating to glandular activity, and it is possible that some of our failures may be due to this cause. It is to be remembered that atrophic changes go on for some months after x-raying has ceased; a myxoedemic condition can be produced. I have known one case in which the patient gradually recovered but had to take thyroid extract for nearly two years; the radiation was given for a skin condition, and the action on the thyroid was accidental. In some quarters it is said that the x-ray dose should be pushed and the softer rays used in spite of the fact that so to do will cause damage to the skin. I emphatically oppose this view. I am sure that the maximum benefit can be got without in any way damaging or marking the skin. I think that if benefit is not got after six to a dozen doses x-ray treatment should be abandoned.

Professor DAVID DRUMMOND (Newcastle-upon-Tyne) called attention to the frequency with which the condition of hyperlymphism was present in cases of exophthalmic goitre, and showed specimens from a recent *post-mortem* case, the patient having died suddenly after operation. The lingual tonsils were much enlarged and the thymus nearly five times the normal size, and in other directions there was great lymphatic increase. This state, amounting to status lymphaticus, he thought would often prove to be the cause of sudden death after operation, and that an attempt should be made to diagnose it. He also referred to the heart and pointed out that when enlarged this generally took place at an early stage; as the case advanced the heart underwent reduction in weight and became dilated, and was frequently the seat of brown induration. He was accustomed, notwithstanding the contrary opinion, to prescribe potassium iodide, and often with considerable benefit. He raised the question of the relationship between the state of hyperlymphism and Graves's disease, and offered the opinion that the symptoms were due not so much to excessive secretion of normal thyroid juice but to an altered (disordered) state of the secretion.

Mr. MARCUS MAMOURIAN (Ashton-under-Lyne) said: I was very struck with the instructive diagram shown by Dr. Wilson and the way he emphasized the critical point—that is to say, the point of maximum improvement under ordinary treatment by rest, etc., and the moment for deciding whether the case should be referred to the radiologist or to the surgeon. All I have to say is that every physician upon whom falls the decision should bear in mind that a course of x-ray treatment would increase the difficulties of the surgeon. Mention has been made of the difficulties of the surgeon. I do not think it fair that the figures of every novice should be included in statistical tables. Mr. Berry gives us 5 per cent. as his mortality rate. It is a magnificent achievement, and as his mortality rate. It is a magnificent achievement, and when one compares the evolution of the Werthorn operation, say, with the one for Graves's disease, I think the surgery of the thyroid may be considered as having made greater strides in the direction of safety. Local anaesthesia should be the narcosis of choice. The use of a local anaesthetic necessitates care and confident technique.

Dr. H. L. TINY (London) asked when a case of exophthalmic goitre could be considered "cured." Under x-ray treatment patients improved markedly in general condition and pulse

rate, and expressed themselves quite well and anxious to return to work, but the exophthalmos persisted and the thyroid was little, if at all, reduced in size.

Lieut.-Colonel R. McCarrison, I.M.S., forwarded from India the following communication, which was read by Dr. H. L. Tidy:

I propose to confine my remarks to a brief reference to the present trend of research regarding the origin of this remarkable disease. Definite knowledge as to its pathogenesis is limited enough, and were it not that the faintest clue may prove to be of importance in the solution of the problem my contribution to this discussion might be summed up in a sentence: We possess as yet but little definite knowledge as to the causation of exophthalmic goitre. I read in an authoritative work, published early in the present year that "the accepted theory as to the pathogeny of the disease is that the disease is due to over-activity of the thyroid, that an excess of thyroid secretion is poured into the circulation." It may be that "overactivity" of the thyroid gland occurs in this disease, and that an excess of thyroid secretion is poured into the blood stream, although for my own part I dislike the terms "overactivity" and "hyperactivity," preferring the more non-committal one of "disordered function." But little as we know of the genesis of Graves's disease we have, I think, sufficient reason to doubt the accuracy of the view that it is due to overactivity on the part of the thyroid gland. Its cause lies deeper than this and is extraneous to the gland itself. In addition to the thyroid other endocrine, glandular, and nervous structures are involved by it and in the production of the symptom complex. I know of no satisfactory evidence that an excess of normal thyroid secretion is actually thrown into the blood stream in exophthalmic goitre. Even removal of the major part of the hyperplastic thyroid, and the relief to certain symptoms afforded thereby, which might be supposed to be evidence of such excess, may be capable of explanation on other grounds. It is true that thyroxin, on subcutaneous injection, will give rise to symptoms similar to some of those present in exophthalmic goitre; but so also will tyramine—including widening of the palpebral fissure. An excess of the latter in the circulation might be suspected as a cause of exophthalmic goitre with as much reason as an excess of the former, did we but transfer attention from the thyroid to other organs and tissues of the body equally involved with it in this disease. I am of opinion that so long as we continue to concentrate attention on the thyroid gland alone, either from the point of view of pathology, symptomatology, or treatment, so long will we fail to understand this disease aright. Even if there be an excess of thyroid secretion in the blood stream in exophthalmic goitre this is the result of the disease-producing process, not the cause of it.

Recently Dr. Emil Goetsch has emphasized the importance of recognizing the early symptoms which as a rule precede the development of the well-known cardinal signs and symptoms of exophthalmic goitre as described in textbooks. Of these prodromal symptoms he accounts weakness or asthenia as an even more important feature than nervousness. "The patient is tired most of the time. She feels tired even without exertion, as on getting up in the morning. The slightest effort is often followed by the greatest fatigue; in fact, the asthenia is so great that the patient will not make even an attempt to do anything." Such is his description of this "early" and "characteristic" asthenia of exophthalmic goitre. For my own part I see in it more reason to suspect adrenal than thyroid derangement. We shall presently be able to judge what evidence the most recent research furnishes in justification of this suspicion.

But first let us consider, very briefly, some of the known facts regarding the incidence of exophthalmic goitre. It is, so far as I am aware, almost unknown in animals either domesticated or wild. Cases have been reported in dogs, cows, and horses, but these are rare, and their true nature doubtful. Nevertheless, I sometimes wonder whether a study of the highly bred, ridiculously fed lap-dog might not fail to reveal examples of it. Recently, a condition of exophthalmos, with great thyroid enlargement and hyperplasia and loss of weight, developed in one of six pigeons that I had fed for long periods on small daily doses of tyramine, but while the bird had exophthalmos in association with a large hyperplastic thyroid—and, therefore, exophthalmic goitre—I am not prepared to assert that the disease was identical with that occurring in man, nor that it was due to the tyramine administered. The almost complete absence of this malady

from animal pathology is a negative fact of much importance, were its cause but known, especially so as thyroidal disease in general is common in domesticated and caged animals. To me it indicates that animals are free of some influence to which highly civilized man is nowadays subjected. Again, exophthalmic goitre is much commoner in females than in males, although the divergence in sex incidence would appear to be less evident in countries where the stress and strain of life is most marked. It is, too, commoner in young women between the ages of 15 and 35 than at other periods of life, and is thus often associated in its origin with the sexual function, an association which is further emphasized by its not infrequent accompaniment in later life with pelvic neoplasms. Has suppressed, excessive, or perverted sexual function or sexual incompatibility anything to do with its onset? In certain cases I have thought that it has. It is most common in improperly nourished young women of the working classes, among many of whom there is a constant struggle between the provision of a sufficient food supply and the demands of personal adornment. Too often their scant earnings are devoted more to the gratification of the latter than of the former. These facts are, however, too general to be of much use to us in the solutions of the problems presented by this malady. What is urgently required is an epidemiological survey of the disease with special reference to thyroidal family history, dietetic history, age, sex, occupation, normal sexual relations, marriage, child-bearing, constipation, gastro-intestinal disorder, previous illnesses, and the like. It is to me extraordinary that so obvious a field of inquiry should for so long have remained unexplored. There is, too, a distinct connexion between various infections and the origin of this disease; while physical, nervous, and mental stress or shock are often determining factors in its onset.

Its race distribution has not been thoroughly worked out, but recently a fact of singular interest in this connexion has come to my knowledge. It is practically unknown among the indigenous inhabitants of India, while they reside within their own country; it is confined almost entirely to the domiciled community in India—to Europeans, to Anglo-Indians, and to Parsees. But despite its rare occurrence amongst Indians who reside in India, cases of exophthalmic goitre were not infrequently encountered in Indian soldiers returning to India from the Western Front during the late war. This fact, taken in conjunction with the high incidence of the disease in western countries, leads me to believe that Graves's disease is pre-eminently a disease of modern civilization, of western modes of life and nutrition, and of the stress and strain and nervous instability which western civilization so often entails.

One turns at once to derangement of the endocrine system for a possible explanation of its genesis, a point to which the earliest, most common, and characteristic symptom of the malady—asthenia—has already directed our thoughts. With this system must be associated the thyroid gland, since, together with the adrenals, it forms part of the endocrine heat-regulating mechanism of the body. Here we begin to find evidence of a more definite order. We know, of course, that Graves's disease is associated with a high metabolic rate and that removal of the thyroid gland will reduce this rate; but almost the whole of the organ must be sacrificed in order effectively to do so. Now by the removal of the thyroid we remove one link in a chain of which the adrenal-sympathetic forms an equally important part; and it is probable that disturbance of this part of the heat-regulating mechanism of the body might be as much concerned in the increased heat production, which is so constant a feature of Graves's disease, as is the disorder of the thyroid. Dr. David Marine (New York) has quite recently provided experimental evidence that this may indeed be the case. He has found that removing or crippling the suprarenals (by freezing *in situ*) results in a metabolic disturbance, characterized by increased heat production and CO₂ output, definitely related to the completeness of removal of the cortical function. The symptom complex somewhat resembles that of exophthalmic goitre. I have had an opportunity to see this work in progress and to examine the suprarenals that had been subjected to freezing; and I find in it a new hope for the more speedy solution of the problems connected with the genesis of Graves's disease. Other observations also are of interest in this connexion. For example, the condition of artificial exophthalmic goitre that can be induced by the anastomosis of the phrenic nerve with the peripheral portion

of the autonomic sympathetic in the cat (Cannon) is associated with an increase in size of the adrenals; a result which in the light of Marino's experiments suggests an attempt on the part of the adrenal cortex to control the excessive sympathetic excitation brought about by the anastomosis.

It has long been known that both in the simple thyroid hyperplasia due to an insufficient supply of iodine, and in that less benign hyperplasia so frequently associated with Graves's disease, the thyroid gland contains less than the normal amount of iodine per gram of gland substance. But whereas in the former the iodine content of the gland can be restored to normal and the hyperplasia dispersed by the administration of iodine it cannot in the latter. Indeed, the administration of an amount of iodine in exophthalmic goitre that would be sufficient to restore the hyperplastic thyroid of simple goitre to the colloid or resting state would be attended with disastrous results. In the former case the hyperplastic organ is still able to control the metabolism of iodine, in the latter it is not; it cannot utilize iodine nor store it normally. There is in exophthalmic goitre a failure on the part of the thyroid epithelium (as shown by J. Rogers) to perform efficiently its metabolic duty with respect to iodine. Now both the work of Marino and of Rogers seems to indicate that this failure on the part of the thyroid is due in its turn to failure of adrenal-sympathetic control; a failure which may be the result either of adrenal disorder or of impairment of the functional integrity of the thyroid terminals of the sympathetic nerves or of both together. For Rogers has shown that by feeding animals with adrenal nucleo-proteins the thyroid gains from 50 to 75 per cent. or more in its iodine content within a few weeks, and that the integrity of the thyroid terminals of the sympathetic nerves is essential to the success of adrenal feeding.

If, now, this failure on the part of the adrenal-sympathetic system, this loss of the "click" exercised by the adrenal cortex on the thyroid function—the adrenal cortex being, as it were, the hand that holds the sympathetic reins to the thyroid—if this failure be indeed a fundamental factor in the production of the symptom complex of exophthalmic goitre, we begin to realize how it may be that conditions of modern civilization can give rise to it, and why it is that asthenia is one of its earliest symptoms; for at this point my own work on the effects of "faulty food" on the adrenal glands and on the sympathetic nerve elements touches that of Dr. Marino. The adrenals are peculiarly sensitive to imperfections in the diet, especially to deficient supply of vitamins, pronounced changes in the adrenal cortex resulting therefrom. Then, too, the health and stability of the sympathetic nervous tissues are similarly dependent upon a sufficiency of these essential substances. If now we turn to examine the meagre evidence afforded by the incidence of this disease, we find that it is most common in precisely that class so subject to overwork and to imperfect feeding, the young women of the working classes in whom, too, the sexual organs so frequently suffer from improper food supply. Add to this accumulation of causal conditions the attacks of such infections as influenza or the presence of alimentary "toxæmia," which are known to exert a deleterious action on the endocrine system, and the way is made ready for the onset of a malady that needs but shock or exaggerated stress and strain to precipitate it. Such a conception of the genesis of Graves's disease emphasizes the probable importance of a nutritional factor in its causation, and gives us some idea of what we effect when, by rest and good food, we so often relieve or cure those who suffer from it. By rest we conserve the resources of the endocrine regulators of the heat-regulating mechanism—resources that are so easily exhausted by overwork, worry, mental depression, and fear; and by the provision of a vitamin-rich food we tend to restore the exhausted function of the adrenal cortex, to prevent the further deterioration of the nervous tissues, and to avert that proneness to sexual disturbance which is so commonly associated with Graves's disease. Let me emphasize here that there is no more common cause than faulty food of disturbance in function of the endocrine regulators of metabolism; and this being so we must ever look to it as the most likely although, of course, not the only foundation upon which metabolic diseases are built.

In these remarks I have endeavoured to indicate the trend which modern research is taking in regard to this disease, without, however, suggesting that as yet we have passed with certainty any definite sign-posts. But the road to success appears more clearly defined, and it cannot but be the wish of

pathologists, physicians, and surgeons alike that research should indicate a more scientific method of dealing with exophthalmic goitre than the surgical sacrifice of an organ so important in the human economy as the thyroid gland. When the reins of control have fallen from the hands of an exhausted driver his horse may bolt; and we may, indeed, effectively stop it by shooting; but it will be admitted that a more economical procedure is to stop the runaway by other means and to restore the exhausted driver.

The chairman, Dr. C. O. Hawthorne, Vice-President of the Section, in summing up the discussion, said that the Section had been fortunate in hearing the views of authorities who spoke on the basis of a wide personal experience. A somewhat remarkable feature of the discussion was the almost entire absence of reference to medicinal treatment. Professor Drummond had said a vigorous word for potassium iodide, but the bromides and such traditional medicines as belladonna and digitalis had been left severely alone. He doubted whether this omission really represented the mind of the profession, though it was possible there was a rebound from therapeutic claims that had been overstated. Another vacant space might be noted—namely, the non-introduction of any proposition concerning the relation of the sympathetic system to the clinical features of exophthalmic goitre. Professor Murray appeared to have disposed of Müller's muscle as an agent causing exophthalmos, and presumably with this disappeared irritation of the sympathetic, so far at least as protrusion of the eyeball was concerned. But while allowing that exophthalmos was due to the accumulation of fat in the orbit, was it not necessary to recognize that not infrequently there was an appearance of protrusion without the reality, as a result of retraction of the upper eyelid? And here, if Müller's muscle was explained away, there remained only contraction of the levator, and for this an explanation was not on the surface.

The opportunity of surgery has been most effectively and judiciously stated by Mr. Berry, and it was a word that could not be challenged. Similarly, treatment by x rays had its undoubted triumphs; while the methods described by Dr. Wilson had the special attraction that they offered a measured or quantitative estimate of the severity or otherwise of the individual case. At the same time it may be claimed that there are not a few cases which can be judged clinically as slight or moderate examples of the disease, and certainly in these, general and medicinal measures, if combined with patience, could expect a considerable measure of success. He would like to have heard more on this point from those engaged in family practice. On behalf of the Section the chairman offered an expression of thanks to the openers of the debate and to others who had taken part in the discussion.

SECTION OF ANAESTHETICS.

W. J. McCARDIE, M.B., B.Ch., President.

PRESIDENT'S INTRODUCTORY REMARKS.

THE PRESIDENT said: I am deeply conscious of the honour of being chosen as President of this Section and of having as Vice-Presidents and Secretaries fellow anaesthetists of the highest reputation. To Dr. Prescott Fairlie, the senior Honorary Secretary, my and your very best thanks are due for the admirable arrangements he has made for this meeting. It is now twenty-five years since I devoted my attention to anaesthesia, and during that period great and rapid advances have been made in the development of our branch of medical science. I understand that the official training of Glasgow medical students in the administration of anaesthetics is still in the hands of surgeons. This seems to me to be an obsolete practice, and certainly is not in the best interests of the students or, more important still, in that of the patients. Advance in anaesthesia has been as rapid as advance in any other scientific subjects, and it is impossible for surgeons, engrossed as they must be in their own work, to follow, practise, or teach modern developments. On the choice of the anaesthetic and on the method of the administration the life of the patient frequently depends. In the progress of anaesthesia my fellow workers in Glasgow and other parts of Scotland have taken a great and honourable share. The position occupied by the anaesthetists of Great Britain now holds a definite and well-recognized importance. This is the

first time that a meeting of this Section has been held in Scotland, and I venture to think that the present one will be the precursor of many other meetings.

DISCUSSION ON BRONCHO-PULMONARY COMPLICATIONS FOLLOWING OPERATIONS UNDER ANAESTHESIA.

OPENING PAPER

BY

DAVID LAMB, M.B., C.M.,

Late Senior Anaesthetist, Victoria Infirmary, Glasgow.

This is the ninetieth Annual Meeting of the British Medical Association, but only the third at which an Anaesthetics Section has been included in the programme of scientific discussions. In 1910 and 1912 discussions on anaesthetics took place at the London and Liverpool meetings respectively, and in October of this year a world congress of anaesthetists will be held under the auspices of the leading societies of anaesthetists of America, at Columbus, Ohio, U.S.A. Anaesthetists, therefore, have reasonable grounds for congratulation on the increasing recognition of the importance of their specialty, both in this country and abroad.

The subject and title of the discussion which I have the honour to introduce were chosen by our President, Dr. W. J. McCardie, and for many reasons I think his choice has been a peculiarly happy one. Out of courtesy to Glasgow it was decided by the committee that a Glasgow anaesthetist should be asked to give the opening paper, and, more out of respect for my advancing years and my lengthy service as anaesthetist to the Victoria Infirmary than on account of any special aptitude for the important task, the honour of doing so has been conferred upon me. I take this opportunity of acknowledging the compliment to Glasgow and to myself.

I have said that the choice of subject is a happy one, and I did so for this reason. The official training of Glasgow students in the administration of anaesthetics differs from that in the great majority of other surgical centres in Scotland and elsewhere in that it still remains in the hands of the surgeons, and special anaesthetists are not yet officially recognized as teachers. One of the results of this arrangement is that, whilst all the expert anaesthetists here use ether freely as well as chloroform, graduates going out into the world from this school know little or nothing of the peace of mind of the anaesthetist engendered by the use of ether. On the contrary, they, or at least those who have come under my observation at the Victoria Infirmary, are to begin with at least

that the administration of ether is followed by bronchitis and pneumonia whilst occasionally patients die on the table under chloroform, far more die after the operation from the above complications when ether is used. If this discussion makes clear that there is no truth, or only the faintest element of truth, in this teaching, it will not have been held in vain, and the way will be paved for the Glasgow graduate of the future approaching his anaesthetic cases without fear and trembling, and he, as well as his patients, will be spared many alarming moments and a few tragic situations. The number of fatalities occurring annually in this city from chloroform in the hands of comparatively inexperienced anaesthetists would probably surprise, if not startle, the adherents of this old doctrine.

The list of broncho-pulmonary complications which may follow operations under anaesthesia is rather a formidable one, including, as it does, acute or subacute bronchitis, bronchopneumonia (so-called ether pneumonia), lobar pneumonia, pleurisy, empyema, abscess and gangrene of the lung, embolism of the lung with or without infarction, and pulmonary oedema, either congestive or acute. In one case, in which the stump of a tooth had slipped unobserved through the glottis, a condition mistaken for phthisis followed, the diagnosis being cleared up later by radiography. It is for us to estimate approximately the frequency of those complications, to discover the various contributory factors in their causation, and to apportion fairly to each its share of responsibility. Accepted opinion on those points will readily suggest means to be adopted towards their prevention when such is possible. The subject is still further complicated by the fact that nowadays we have not only the inhalation of

nitrous oxide, chloroform, and ether to consider, but also that of chlorido and bromido of ethyl, local anaesthetics, spinal analgesia; the intratracheal and rectal administration of ether, the intravenous use of ether, hedonal, etc., and the advantage of warm vapours as against that at ordinary temperature.

In a paper limited as this one is by the regulations of the British Medical Association, it is manifestly impossible to discuss every branch of this subject in detail. I would suggest, therefore, as points for discussion the types of broncho-pulmonary complications met with, the frequency of their occurrence and their causation, with which latter is naturally associated the question of prevention.

BRONCHITIS AND PNEUMONIA.

Occasionally a patient is for a few days after operation "ehesty." He has a slight cough, with or without expectoration and without pyrexia, the result of mere irritation of the upper air passages or of very slight bronchial catarrh. Mr. Parry first drew my attention to a condition occasionally following operations, more especially urgent abdominal cases, a condition which at first alarmed him but which later on did not give him much concern—a condition with which most surgeons must be familiar. On the day after operation the temperature rises to about 100° F., and the patient complains of slight roughness, tightness, or oppression about the chest. He has a slight cough, which he is compelled to restrain on account of the pain in the abdominal wound, but he never appears to be very seriously ill. The temperature may rise to between 101° and 103° and usually lasts only three or four days, when with the greater ability to cough, mucopurulent expectoration, sometimes very free, takes place, and the condition rapidly subsides, though it may last for several days longer. The cause of this complication, which occurs occasionally apparently without symptoms other than pyrexia (when it is probably vaguely referred to as "post-operative reaction"), has been investigated at the Presbyterian Hospital, New York, by Whipple,¹ who has carried out a good deal of original research work on the radiographic method of studying post-operative pulmonary complications. Those cases seem to be cases of abortive pneumonia, the radiogram showing a distinct shadow, wedge-shaped to begin with, the base towards the pleural surface, and more frequently in the lower lobes of the right lung. Occasionally the shadow is seen a day or two before the development of any physical sign of lung implication, and usually both shadow and physical signs disappear in one to three days. Bronchial breathing may occasionally be absent if the area of consolidation does not extend all the way from the periphery to the neighbourhood of the larger bronchi near the root of the lung. The biological classification of the pneumococcus by means of immunity reactions has established the fact that pneumococci can be divided into at least four groups. Groups I, II, and III may be called parasitic, inasmuch as they do not occur in the throat except pathologically, while group IV may be looked on as saprophytic and is found in at least 60 per cent. of normal throats. According to Whipple, it is now well recognized that as the result of the work of Neufeld and Haendel, elaborated by the investigators at the Rockefeller Institute, groups I, II, and III are the exciting organisms in the severe typical medical pneumonias, and that group IV is the more usual finding in the majority (70 per cent.) of post-operative cases, and especially the shorter atypical forms of the disease referred to above. In the remainder the exciting organisms included the I, II, and III groups of pneumococcus, the *Bacillus influenzae*, a streptococcus, and the *Bacillus mucosus capsulatus*. In an increasingly large number of the patients developing this type of disease there is found pneumococcus IV, both in the pre-operative and in the post-operative sputum. The germs in the mouth and pharynx get mixed up with the excess of mucus and saliva, and infection of the bronchi results—a view which is in support of that of Höltscher on the origin of those complications. In Whipple's cases lobular pneumonia was from two to three times more frequent than lobar. In addition to this comparatively mild complication all the ordinary forms of pneumonia and bronchopneumonia may be met with, the exciting organisms being those referred to above, though the great majority of the later pneumonias are septic in origin.

Frequency.

Most of the older statistics available are of little real value, as from the extreme divergence of their findings they can hardly be looked upon as reliable. They do not distinguish

between minor and major operations, nor do they differentiate between clean and septic cases. One must remember also that when any pulmonary complications follow other they are usually at once described as ether pneumonias, but if after chloroform they are ascribed to some other cause. Discussions on this question were held by the Society of Anaesthetists in 1900 and 1903, and the results are recorded in their *Transactions* (vols. iii, iv, and v). Extremely varied opinions were expressed by the leading anaesthetists of London.

Cooper and Cronch² gave an interesting report based on close personal observation of 2,400 patients at St. Thomas's Hospital. Ten cases (one fatal) to whom ether had been given developed temperatures with respiratory trouble within twenty-four hours. Practically all occurred after long operations, especially those in which free expectoration was interfered with by bandages or the position of the patient, and they included 4 cases of hernia, 2 breast cases, and one case of varicose veins. In none of the cases was the anaesthetic administered by the staff anaesthetists, this being done by the less experienced house officers.

Smith, of Liverpool,³ in 221 major operations with warmed ether and chloroform and 220 minor vaginal operations with open ether, gave a morbidity of 7.5 per cent. in major and 2.2 per cent. in minor operations. The great majority were coughs without physical signs, the remainder, 1.1 per cent., being cases of bronchopneumonia.

Alma Vedin,⁴ of New York Hospital, gives a review of 7,900 operations. There were 120 post-operative pulmonary complications, or 1.51 per cent. These complications comprised lobar pneumonia, bronchopneumonia, acute bronchitis, pleurisy (acute fibrinous, sero-fibrinous, and suppurative), and embolism of the pulmonary artery. There were 29 deaths in these 120 cases, including 10 deaths from pulmonary embolism, a total mortality of 0.36 per cent. of the 7,900 operations. Lobar pneumonia was by far the most frequent complication; nearly all cases followed abdominal operation, and the incidence was relatively greater after operation in the upper abdomen, though several followed appendicectomy (19 per cent.) and hernial repair (33 per cent.). The anaesthetic used was ether alone or preceded by gas or ethyl chloride, except one case with gas oxygen and one with no anaesthetic.

Whipple¹ reported 97 cases of pulmonary complications in 3,719 carefully observed post-operative cases (2.6 per cent.) in 1915 and 1916. In his opinion general statistics regarding the incidence of this complication in different clinics vary largely with the care given to its detection. He gives a table of reports by nine different observers in which the morbidity detected in coeliotomies varied from 0.5 to 8 per cent.

Causation.

In my experience at the Victoria five cases of lobar pneumonia followed that at the time of operation four were suffering from "colds in the head," and the fifth had recently recovered from influenza. Two had chloroform only and three C_2E_2 and chloroform. At that time patients on the operating table were covered only by a sterilized sheet, and were brought from and returned to the ward with a "theatre blanket" as practically their only covering. Since then, with the exception of one case (my one fatal case, to which I shall refer later), I think the surgeons will support me when I say that there has been extremely little pulmonary trouble attributable to the anaesthetic, a statement borne out by the records of the *post-mortem* room. The fact that the Victoria Infirmary is ventilated by the Plenum system, and that there are no cold corridors or open windows, is perhaps worthy of note. C_2E_2 was the anaesthetic of choice until 1910, as—brought up as it were on chloroform—Clover's apparatus in the pre-atropine days, with its cyanosis, excessive mucus and saliva, never appealed to me. Afterwards open ether or chloroform were the routine agents, with the various special methods when the use of these was indicated.

By the courtesy of Dr. Anderson, our pathologist at the Victoria Infirmary, I have been able to analyse the reports of 1,031 consecutive *post-mortem* examinations from the surgical wards. I was much impressed by the large number (fully 70 per cent.) of patients who showed evidence of chronic bronchitis and emphysema, pleuritic adhesions sometimes very extensive, or other indications of past or chronic lung mischief. In a large proportion also passive congestion—in three cases definite hypostatic pneumonia—and oedema of the

lungs were apparently terminal features of the cases. In this series there were:

- 7 cases of pneumonia following accidents—no operation.
- 5 cases (acute bronchitis 3, pneumonia 1, double pleurisy 1) in other surgical conditions without operation.
- 24 septic pneumonias in cases of osteomyelitis, peritonitis following operations for perforated gastric or duodenal ulcer, gangrenous appendix or gall-bladder cases, cellulitis, prostaticectomy with pyelitis, etc.
- Others in cases without evidence of sepsis: 2 pylorectomies for malignant disease and 1 excision of malignant gastric ulcer, all in patients already weak and emaciated; 2 strangulated hernias in patients aged 64 and 70; 1 colostomy for cancer of the colon in a patient aged 76.

In the 24 septic cases the pneumonias were definitely septic in origin, the infective organisms having attacked the lungs from the infected blood stream. In the last group, when one considers the condition of the patient, the clinical history, and the nature of the case generally, the part played by the anaesthetic must have been infinitesimal, so that, so far as fatalities are concerned, the anaesthetic comes out of the inquiry practically "without a stain on its character." When a surgeon tells you that his patient died of bronchopneumonia ten days after operation and that you should have given chloroform instead of ether do not worry too much. There may have been another explanation. Incidentally I might mention that in this series of *post-mortem* examinations not a single case showed any evidence of delayed chloroform poisoning, although Dr. Anderson was always on the look-out for it.

Although more intimately connected with a later part of this paper I shall just enumerate the other pulmonary complications found in this series. There were 8 empyemas, 15 pyemic abscesses of the lung (7 gangrenous), 16 infarctions, and in addition there were 10 cases of thrombosis (in the iliac, femoral, portal, renal, and pulmonary veins and inferior vena cava). All were associated with grossly septic conditions except two cases of thrombosis and two infarctions, the latter after operations for inguinal hernia and varicose veins, the former after operation for varicose veins and excision of the kidney for malignant disease.

From the experience referred to previously I became strongly of opinion that the most important contributory cause of early post-operative pulmonary trouble was the presence of some more or less recent catarrhal affection, mild or otherwise, of the upper air passages of the patient prior to the operation. In this connexion I would point out also that the presence in the operating theatre for any length of time of any individual suffering from an acute nasal catarrh is, unless he is well masked, a danger to the patient and to all others present. On several occasions I have seen a "cold" run through a whole theatre staff, the affection being traceable to such a cause. The factor next in importance is undue exposure to cold and consequent "chill."

According to the textbooks the usual causes of ordinary bronchitis and pneumonia are chill and exposure, which, by lowering the vitality of the tissues, render them more liable to the attacks of the ubiquitous pneumococcus, etc. All the circumstances of an operation lend themselves to possible chill and exposure unless constant care and watchfulness are exercised. There may be unnecessary exposure during the preparation (shaving, bathing, etc.) prior to the operation, the patient actually catching cold after his admission to the hospital or nursing home. An inexperienced nurse may bring him, insufficiently covered, along cold corridors to wait some time in the anaesthetic room. In the theatre, the temperature of which may not always be all that could be desired, he may be exposed for an hour or two on the operating table with the abdominal contents or an extensive wound exposed. Then comes the return to the ward along draughty corridors, or, as I have seen even in this country, along an open veranda, into a room insufficiently heated or with widely opened windows regardless of the weather. The wonder is not that pulmonary complications arise, but that they do not arise more frequently. All this tends to lower the temperature of the patient and aggravates the fall which frequently occurs during a long and severe operation, and thus the patient's vitality and resistance, possibly already reduced by disease, starvation, loss of blood, or shock, are still further impaired.

By far the majority of post-operative pneumonias, more especially those occurring several days after the operation, are associated with sepsis, the infective organism being carried to the lungs free in the blood, or by the lymphatics

from some septic area, or in an embolus from an infected thrombus. Anything tending to cause limitation of the respiratory movements and consequent tendency to congestion of the lungs constitutes another contributory factor, and here the pain of an abdominal wound and tight bandaging round the chest or abdomen are the most common influences at work. The remedy for the latter readily suggests itself, whilst for the former some surgeons favour the local use of quinine and urea. At the beginning or the end of the operation, however, the lungs may also occur as the result of circulatory depression from the toxic effect of the anaesthetic, chloroform being the most dangerous on account of its depressant action on the heart and blood vessels.

Then we have the class of cases described as "aspiration" pneumonia or bronchitis, in which, usually in "obstruction" cases, but also possibly during the recovery from the anaesthetic before the complete return of the reflexes, vomited material or blood is sucked into the lungs. In this class may be included those cases in which there is hypersecretion of mucus and saliva, which become saturated with the anaesthetic and which may act as a vehicle for the conveyance of organisms from the mouth downwards. This, however, thanks to the routine use of atropine, is now rarely troublesome. Cases have been ascribed also to the irritant effect of impurities in the anaesthetic. At a meeting of the Scottish Society of Anaesthetists one member referred to an outbreak of pulmonary complications due to the use of commercial ether, supplied, unknown to the anaesthetist, by the chemist with a view to economy.

What, then, is the part played by the anaesthetic in the causation of the complication under consideration? In this country opinions vary, but it is, I think, generally accepted that nitrous oxide gas is non-irritant and that the vapour of chloroform is much less so than that of ether, whether warmed or at the ordinary temperature. The consensus of opinion seems to be that it is only the prolonged exhibition, more especially of concentrated vapour of ether, which gives rise by direct irritation, or by chilling due to evaporation, to any real danger. This also was the general opinion at the discussion on ether pneumonia by the Society of Anaesthetists in 1900. Shipway,⁵ however, expresses the opinion that—

"Ether, when given by modern methods (warmed vapour), is known to be capable of sustaining the blood pressure over long periods, and to have rid itself of its former reputation of setting up irritation of the lungs."

Abroad, also, opinions differ on this point. Flagg,⁶ of New York, in a personal communication, says:

"The theory that ether *per se* gives rise to an irritation which leads to post-operative pneumonic complications appears to have been abandoned as untenable. It is a quite genuinely accepted fact in the circles wherein I work that there is no such thing as ether pneumonia, that the post-operative pneumonia which we see is due to exposure before, during, or after operation, the development of an infection already present or of embolic origin. In operations on the nose or throat a certain number of cases probably occur through aspiration, when suction is not employed."

He finds that there are definite seasonal occurrences of pneumonic complications, and refers to a series traced to a single ward notoriously draughty and old-fashioned in its appointments.

Mikulicz⁷ (quoted by Rovsing⁸) had, on account of the somewhat frequent occurrence of post-operative pneumonia, deserted ether for chloroform, in the belief that the pneumonia was due to the irritating effect of ether. To his surprise, however, he met then with a still greater percentage of post-operative pneumonia. He changed to local anaesthesia in all cases, and to his still greater surprise found that lung complications increased instead of decreased (27 cases in 114 laparotomies). Naturally this experience overthrew the conception that post-operative pneumonia was "narcosis" pneumonia. The great majority followed abdominal operations. According to Mikulicz also it has been proved experimentally with animals, and he has substantiated the facts by experiments, that whilst other occasions increased salivation, the air passages—larynx, trachea, and bronchi—are not irritated at all, even when the animals were killed by administering ether through a tracheotomy tube. According to Whipple, on the other hand, "there is no doubt that ether is the anaesthetic most irritating to the mucous membranes of the oropharynx, particularly when there is any acute or chronic inflammation at the time it is administered."

From repeated personal experience I know that if I am just recovering from a nasal or bronchial catarrh any attempt to administer ether to a patient by the open method, involving, as it does, my inhaling some of the vapour, soon sets up very troublesome cough and increased secretion of mucus or muco-pus, which seems to come from below the glottis. When using chloroform or Shipway's apparatus, with which there is less contamination of the atmosphere of the theatre, the same effect is evident, but much less marked. When I am perfectly free of catarrhal symptoms no such effect is produced. I always look upon this as due to the irritant effect of ether vapour acting on the mucous membrane of my upper air passages, which at the time is in a specially susceptible condition.

Recently in a nursing home I anaesthetized a gentleman about 50 years of age, for operation for double inguinal hernia. There was considerable excitement during the induction of anaesthesia, which was effected by means of chloroform followed by open ether, but as there was a somewhat free secretion of mucus and saliva, in spite of the use of atropine, the latter part of the operation was completed under chloroform. Within four or five hours a condition resembling acute oedema of the lungs was present. This continued next day, and the patient died within forty-eight hours with severe dyspnoea and excessive mucopurulent expectoration. On investigation it was found that the patient was probably alcoholic, that a year before he had suffered from a prolonged attack of bronchopneumonia, and that he had just recovered from a "severe cold" a week prior to the operation. There was no albuminuria. Unfortunately there was no post-mortem examination, but I cannot absolve the irritant action of the anaesthetic from at least a share in the catastrophe.

It seems to me that the vapour of ether, and of chloroform to a very much less degree, is certainly an irritant to the lining membrane of the upper air passages and bronchi, but extremely rarely sufficiently so—unless unskillfully administered—to set up a purely irritant bronchitis or bronchopneumonia similar to that caused by the poison gases during the late war. But where there is any weakening of the resistance of those tissues, the result it may be of congestion due to chill or lowered vitality, or to the presence of a mild catarrhal condition, or to a combination of those conditions, this comparatively mild irritant action, more especially of ether, may act as the "last straw" and lead to the overwhelming of the natural antibodies by the ever-present pathological organism which the healthy tissues are under ordinary circumstances able to resist.

Whilst, therefore, it may be correct to say that the anaesthetic *per se* rarely if ever sets up a bronchitis or bronchopneumonia, it is wrong to maintain that it is always a perfectly innocent agent in all such cases after operation. One would naturally expect the use of warmed ether by Shipway's or other apparatus to be even less harmful, but when one considers the extreme variations of temperature with which the mucous membranes of the air passages frequently contend in everyday life without harm resulting, one does not feel inclined to press this point unduly. I hope, however, to hear some evidence on this point from some of the members present. The same remark applies to the use of ethanesal.

It is not only the direct effect of inhalation that we have to consider, but also the effect during excretion, the great bulk of which takes place through the lungs. I know of one case in which one pint of saline containing 5 per cent. ether was administered to a youth intravenously, and in which acute oedema of the lungs occurred within a few hours. A case⁹ has been described also, in which ether was administered *per rectum* to a gentleman of 58 with malignant disease of the larynx, which quickly proved fatal with signs of excessive irritation not only of the intestine but also of the bronchial mucous membrane.

In support of the view that the great majority of post-operative pulmonary complications may and do occur quite independently of the anaesthetic, it is found that such cases also occur after operations under local anaesthesia and spinal analgesia. I have not seen this occur, but my experience is comparatively limited. One must remember, however, that those methods are frequently reserved for cases in which pulmonary troubles are present or anticipated. Rood,¹⁰ however, with a personal experience of 8,000 cases, states that he has seen both bronchitis and pneumonia follow the use of local anaesthesia. Acute septic conditions, such as appendicitis and osteomyelitis, were generally present in those cases in which pneumonia followed the use of stovaine. Whipple¹ records also six cases under local anaesthesia with novocain two of them being in cases giving a history of recent recurrent colds.

So far I have dealt with catarrhal and pneumonic conditions, and have still to refer to some of the other post-operative pulmonary complications, the majority of which, in my experience, are associated with sepsis.

PLEURISY, EMPYEMA, AND ABSCESS OF THE LUNG (FREQUENTLY GANGRENOUS).

These complications are usually associated with sub-diaphragmatic abscesses connected with septic gall bladder or appendix cases, perforated ulcers of the stomach or duodenum, malignant growths in the upper abdomen, or they originate as the result of embolism from other septic areas, whilst cases of acute oedema of the lungs are, according to Buxton,¹¹ usually associated with some pathological condition of the kidneys. In some of the Victoria Infirmary cases of empyema and abscess of the lung associated with abscesses in the upper abdomen there was a definite perforation of the diaphragm, admitting a thick probe, whilst in others there was no perforation, the septic process having permeated the tissue of the diaphragm throughout its entire thickness. In others, again, the extension had taken place by way of the lymphatics. Abscess of the lung is of occasional occurrence also after tonsillectomy, though rarely after other operations, even when extensive, in the mouth and throat. Brown Kelly,¹² at Newcastle last year, described one such case after tonsillectomy, and referred to a considerable number of others. He quoted two explanations which have been given of this occurrence:

1. Aspiration of blood containing septic matter squeezed out of the tonsillar crypts during operation. This view is supported by the following facts. Almost all were operated upon under general anaesthesia whilst lying on the back (Gwathmey has collected four cases under local anaesthesia); in the majority signs and symptoms developed within thirty-six hours, the abscess was solitary, and, as a rule, in the lower or middle lobes of the right lung.
2. According to the other view, septic thrombosis of the veins in the tonsillar bed is followed by pulmonary infarction. This explanation accounts for the minority of cases (Gwathmey, 1 per cent.) in which there is no trouble until after the lapse of from four days to two weeks.

PULMONARY EMBOLISM AND INFARCTION.¹³

These complications occur probably much more frequently than is generally supposed, and the great majority are met with in patients over 45 years of age, and usually after abdominal operations. The site of thrombosis has been found to vary, but usually it is in the iliac or femoral veins or in the inferior vena cava. The conditions predisposing to thrombosis are loss of fluid from starvation, purging, haemorrhage, post-anaesthetic vomiting, etc., sluggish circulation due to shock or anaemia, the more or less fixed recumbent position, damage to vessels, or to sepsis. The time of occurrence is most commonly from five to ten or twenty days after operation. In one series in the Mayo clinic 19 took place in the first week and 21 in the second. With regard to frequency, Lockhart-Mummery quoted 47 fatal cases of embolism in 63,573 cases in the Mayo clinic (36 pulmonary, 10 cerebral, and 1 coronary). Victor Bonney recorded 5 cases in 1,791 hysterectomies, and 2 in 1,410 ovarian and tubal operations, whilst there were none in ventrofixation or vaginal cases, and he remarked upon the relative frequency after uterine operations. Spilsbury found 9 deaths from pulmonary embolism in 1,013 consecutive post-mortem examinations at St. Bartholomew's Hospital. In Johns Hopkins Hospital there were 31 deaths in 21,000 cases, but as Lockhart-Mummery estimates that probably only 1 in 10 cases is fatal this complication is not a rare one.

Blocking of the pulmonary artery by a large embolus, leading to sudden death before there is time for the formation of an infarction, occurs usually in patients who have had an otherwise normal convalescence. In cases of infarction due to small emboli a low grade of inflammation in connexion with the wound or with phlebitis usually precedes the onset and the convalescence has not been quite satisfactory (Gordon Watson).

PREVENTION.

If the various factors to which I have referred are admitted to be the exciting or contributory causes of post-operative pulmonary complications, measures for their prevention will readily suggest themselves. I shall merely enumerate those which in my opinion are the most important.

1. An experienced anaesthetist should be employed, as he is more likely to avoid the use of a too concentrated vapour and the administration of ether in cases in which its use, prolonged or otherwise, is contraindicated.
2. Give atropine sulphate an hour before operation in all cases.

3. If there are any symptoms or signs of nasal or bronchial catarrh, postpone the operation if at all possible. If this cannot be done, or if there is only a history of a recent cold or influenza, carry through the operation as quickly and as gently as possible, and take every precaution to prevent chilling before, during, or after the operation. In all such cases use local anaesthesia or spinal anaesthesia when possible, otherwise give chloroform, or nitrous oxide and oxygen if absolute and continuous relaxation is not essential. Unless specially indicated avoid the use of ether in such cases. Chloroform in the hands of experienced administrators, though not so safe as ether, is not nearly so virulent a poison as it is alleged to be by some American writers.

4. In abdominal and breast cases apply bandages lightly. Raise the head of the bed as early as possible and encourage the patient to clear away any mucus which may be present in his air passages.

5. In all cases have the patient carefully and continuously watched during his transit to bed and afterwards until his reflexes have returned sufficiently to prevent aspiration of vomited material into the trachea.

6. In operations on the upper air passages take every precaution to prevent, both during and immediately after the operation, aspiration into the trachea of any foreign material such as blood, mucus, or pus, and in dental cases let every stamp be accounted for. In all such cases the patient on his return to bed should be turned well round on his side until his reflexes have returned, to allow the escape of blood from the mouth by the action of gravity.

7. Unless absolutely necessary, do not, on a cold winter night, rush an acute appendix case out of his warm bed on his way to nursing home or hospital. The staff are tired, and therefore not so efficient, and the theatre and corridors probably cold.

8. When indicate 1, as in intestinal obstruction and some cases of peritonitis with vomiting, have the stomach washed out, preferably prior to the administration of the anaesthetic, but certainly before the operation is begun, and repeat the process during the operation if necessary.

In closing this paper, gentlemen, I would put forward the suggestion that one or more subjects for discussion next year should be decided upon at this meeting, that a questionnaire be drawn up by our president and secretary at their convenience, and that this should be circulated to anaesthetists at the principal surgical centres of this country. This close, personal, well-directed observation by a moderate number of anaesthetists over for six months would result in the accumulation of a valuable store of reliable, up-to-date information.

DISCUSSION.

Dr. Dickinson Beary (London) was inclined to believe that "other bronchitis" was somewhat of a myth. The anaesthetic was always open to blame for such an accident, "ear les absents ont toujours tort." In order to prove that the anaesthetic was the primary cause of post-operative chest trouble the possibility of sepsis connected with the wound must be eliminated, as well as the chance of chill or other infection. In her own experience as anaesthetist to two large hospitals she could recall no case of chest trouble directly attributable to the anaesthetic. She produced statistics of 1,411 cases of thyroidectomy operated upon by Mr. Berry in which careful notes had been kept of the post-operative condition. The anaesthetic used had altered with time: from 1888 to 1907 anaesthetic used had altered with time: from 1888 to 1907 it had been almost exclusively chloroform; from 1908 to 1912 open ether preceded by chloroform had been mainly used; and after 1912 ether alone by the open method had been the sole anaesthetic in 600 cases. Among the 1,411 cases there were also 47 cases of local anaesthesia by novocain. Only 6 cases were found in which there was mention of lung or throat trouble: (1) Slight pneumonia accompanied by local sepsis, the wound being reopened on the fifth day. (2) Bronchitis for a few days after operation in a lady who had been subject to bronchitis before; primary union occurred. In both these cases the anaesthetic was chloroform. (3) A case of bad dyspnoea; bronchitis, present before, considerably aggravated after operation. Local anaesthetic, preceded by chloroform. (4) Slight bronchitis, clearing up in a few days; primary union of wound. Anaesthetic—ether, preceded by chloroform. (5) Mild sepsis, slight bronchopneumonia occurring on the sixth day in a pregnant woman with urgent dyspnoea, whose temperature was 100° before the operation. Anaesthetic—open ether. (6) In this case the ether appeared sedative;

rapid general improvement immediately followed operation in a patient with ribs all over the chest at the time of operation. Twenty-one cases of intratracheal ether at the Royal Free Hospital for thyroidectomies for other surgeons were also cited. In these there were five cases where sore throat and cough were noted; one of these led to septic tonsillitis and another had signs in the chest and pyrexia lasting for a week. Doubtless in those cases the cause of the trouble was irritation or sepsis due to the passage of the tube. In conclusion the speaker held that though chest trouble was probably rarely due to the irritation of the anaesthetic vapour, this latter might reasonably be a contributory factor, either by facilitating the sucking in of septic matter, as when there is much secretion of mucus, or by producing diminished resistance in the patient to outside influences. From this point of view chloroform was likely to be more deleterious than ether, being as a rule more depressing, and it was open to question whether severe operations under a local anaesthetic did not at times produce a more depressed condition than if general anaesthesia had been used. Dr. Berry believed that in connexion with after-effects it was very important to maintain as light an anaesthesia as was compatible with operation.

Dr. A. L. FLEMING (Bristol) drew attention to, and criticized the use of, strong solutions of cocaine in laryngeal surgery. There was increased risk of aspiration of septic material into the lungs when the laryngeal reflex was abolished by the use of strong solutions of drugs of the cocaine type. He also made a plea for the anaesthetist to be called in and consulted in cases where complications occurred which could be in any way attributed to the anaesthetic. Such complications were frequently aggravated by the injudicious use made of strong expectorants of the type of ammonium carbonate. Their exhibition resulted in the patient being drowned in his own lung secretions instead of relieved. He believed that many complications could be avoided by attention to posture of the patient after operation and during recovery.

Dr. PATON BOYD (Glasgow) remarked on the frequency of pulmonary complications in high abdominal operations, especially those on the gall bladder. He believed that there was a type of "chesty" individual who was especially susceptible to "chesty" conditions, and even chloroform would not help in this type of case. There was also a tendency for complications to occur in runs, and the explanation of this phenomenon was to be sought for in external conditions such as draughty corridors or catarrhal epidemics.

Mr. HERBERT J. PATERSON (London), speaking as an operating surgeon, declared that any person using chloroform without sufficient reason should be criminally prosecuted. Gas and oxygen should be used for abdominal operations, even at the expense of the surgeon in the matter of discomfort and increased operative difficulty due to increased rigidity, and he personally made much use of this anaesthetic even for severe abdominal cases. He believed that a time would come when only urgent operations would be performed in cities and that this was the ideal to aim at. Hospitals should be erected in the open country and only casualty clearing stations left in the towns. Lung complications could be minimized by proper deep breathing exercises, and these should be undertaken both prior to and following operation.

Dr. H. FEATHERSTONE (Birmingham) presented an analysis of 313 consecutive medical and surgical *post-mortem* examinations made at the Birmingham General Hospital, the results throwing some light on the causation of broncho-pulmonary conditions following operations. The hospital in which all cases were operated upon was ventilated by the Plenum system. Of 135 post-operative autopsies 62, or 45 per cent., had definite bronchopneumonia, whilst of 144 non-operative cases, excluding primary medical pneumonias, 42, or 29 per cent., showed this complication. He concluded that pneumonia was a frequent terminal condition, but was much more common in severe post-operative conditions than in similar "medical" cases. Professor Shaw Dunn, by whose kind permission the analysis was undertaken, believed that the majority of surgical cases showed evidence of aspiration pneumonia. In 50 per cent. of the post-operative cases the lower lobes only were affected, whereas of the non-operative cases only 20 per cent. showed affection of the lower lobes alone—that was to say, most severe operations have a specially injurious effect on the lower lobes. The anaesthetics employed in these cases were: open or closed ether in 21

(33 per cent.); mixture (E_2C_2) or chloroform in 33 (50 per cent.); local or spinal in 4 (7 per cent.); N_2O and O_2 in 3 (5 per cent.); intratracheal ether in one. It was noteworthy that in a hospital where ether was given as a routine, in only one-third of those cases of bronchopneumonia was it employed, while chloroform or a mixture was used in half the cases. Each of the post-operative cases in which bronchopneumonia was found at autopsy had sustained at least one of the five sources of severe shock and exhaustion—namely, septicaemia, embolism, upper abdominal operations, severe general peritoneal shock, or aspiration of septic material from nose and throat. Septicaemia was present in 20 cases (32 per cent.); non-infective thrombosis and embolism in 2 (3 per cent.); upper abdominal operation in 28 (45 per cent.); severe general peritoneal shock in 11 (15 per cent.), including appendicitis and general peritonitis in 7, volvulus in 2, radical carcinoma recti operations with some degree of septicaemia in 2; aspiration of putrid mouth and nose contents after operation for malignant growth of the tongue, jaws, or nose in 3 (5 per cent.) (but in this connexion it must be noted that in over fifty consecutive operations of greater or less severity on the nose and mouth, performed with the patient sitting in a chair, intratracheal methods have abrogated aspiration pneumonia, the cough reflex being always allowed to return before removing the catheter). He wished to emphasize his opinion that ether, even though given cold and concentrated, played but little part in the causation of bronchopneumonia. In the ear and throat department of the hospital, 690 consecutive operations were performed, and with few exceptions the anaesthetic was ether, administered by Rood's intensive method; and no case developed any trouble of such severity as to be recorded. In the gynaecological department operations were prolonged, anaesthesia deep, and haemorrhage sometimes severe, but there was rarely any considerable upper abdominal shock, sepsis was uncommon, and owing to the Trendelenburg position aspiration of oral contents was prevented. In 262 operations only 3 cases of bronchopneumonia occurred. One commenced four days after operation in an old and feeble woman, one was well established before operation in a case of severe upper peritoneal shock due to ruptured tubal gestation, a spinal anaesthetic being employed. The third had profuse lung secretion during the recovery stage, which presumably led to lung infection from a long-standing purulent nasal discharge. It was in the surgical abdominal wards that lung sequelae might be expected, and it was there that they were found. Of 62 bronchopneumonia autopsies 28, or nearly 50 per cent., had undergone operations on the upper abdomen. Harmful reflexes from the peritoneum of that region might produce spasm of the bronchioles or might give rise to paralysis of the diaphragm with collapse of the lower lobes of the lungs. That the diaphragm was at fault might be demonstrated by radiography. Further, pain in the wound might prevent coughing to clear the lungs. Such patients were often poorly nourished owing to some wasting disease (for example, gastric ulcer or new growth), sustained severe peritoneal shock, their diaphragms were relaxed, blood loss might be severe, chill from body exposure might occur, and so general resistance to infection was very low. All that was necessary to ensure a bronchopneumonia was a suitable infective organism, especially in certain surroundings and at special seasons. In summer, and in well-warmed private rooms, respiratory complications were rare, even in exhausted and shocked patients, but they were much more common in crowded hospital wards in the seasons of colds. In March of this year 6 cases of bronchopneumonia occurred in the abdominal wards, while only 2 cases were noted during the following three months. In conclusion, he briefly summed up the predisposing factors which he believed he had shown to lead to lung complications.

In the unavoidable absence of Dr. J. STUART ROSS (Edinburgh) his analysis of 484 cases completed during the first year of his war service in the Balkans was read by the local honorary secretary, Dr. FAIRLIE. Notes of the cases had been carefully kept with a view to elucidating the causation of the sequelae of ether and chloroform.

The series did not include any nitrous oxide cases. All were males, mostly young, many were heavy cigarette smokers, some were in a gravely septic condition, and a large number of them had chronic naso-pharyngeal catarrh. All these factors made for a high post-operative morbidity rate from bronchitis or pneumonia. There were but few cases of abdominal surgery, and in the whole series definite

respiratory sequelae occurred in but 21, giving a morbidity rate of 4.3 per cent., which was curiously near the figure given by Smith in the paper quoted by Dr. Lamb, though Smith stated that the rate was only 2.2 per cent. among non-abdominal cases and 7.5 per cent. among abdominal ones. This therefore meant that the rate was roughly twice as high in his (Dr. Ross's) cases, as most were non-abdominal. In the 21 cases mentioned, 3 were lobar pneumonia, of which 1 was fatal. The last was a man in a gravely septic condition from a gunshot wound of the arm and thigh, and pneumonia developed forty-eight hours after leaving the theatre. The anaesthetic was chloroform and ether from a Shipway machine; the administration was for twenty minutes only, and during administration no warning symptoms of respiratory irritation appeared. If this was a true post-anaesthetic pneumonia and not a septic one, the total mortality rate was therefore 0.2 per cent. in the series. Nearly all the cases received a preliminary dose of morphine and atropine, but in many cases it was administered so near to the operation that time was not sufficient for it to develop its beneficent action. In 125 cases the anaesthetic was chloroform mainly or solely. In 295, ether was used mainly or solely. In 64, a mixture of the two was given intentionally. An open drop method was used in 158 cases, and a Shipway in the remaining 326. Of the 21 cases with respiratory sequelae, 10 had received chloroform, 7 ether, and 4 a mixture.

From these figures it might be argued that chloroform was twice as likely to cause sequelae as ether, but then it must be remembered that in all cases where sequelae were feared chloroform was chosen. The proper conclusion to draw was therefore that chloroform would not necessarily avert sequelae where post-operative trouble was feared.

In the series under discussion the warmed vapour cases bore to the open drop method cases a relation of very nearly 2 to 1. Among the cases where pulmonary complications occurred the relation was 16 to 5, or nearly 3 to 1, so that the protection afforded by warming vapours was not absolute. Note was taken of any bronchial or tracheal mucous rales appearing during administration to a degree more than trifling, and this occurred in 49 cases, in spite of adequate "morphiatropization," and showed the high average irritability of the respiratory mucous membranes of the serving soldier. These 49 cases yielded 4 of the total 21 respiratory sequelae, indicating that mucous rales appearing during anaesthesia indicated about a doubled chance of trouble afterwards, though such troubles developed even when no irritation was shown. In 52 of the cases there was either acute nasopharyngeal catarrh or definite tracheitis or bronchitis present before operation, and this factor was really pathogenic, for among them no less than 11 developed quite marked trouble afterwards, and quite half of the 21 cases with sequelae had some infection before operation. In the writer's opinion this was cause and effect. Most of the cases showed little more than a slight cold in the head at the time of operation, and it was not the cases with definite bronchitis which gave most trouble later. Such men have already manufactured their antibodies, in all probability. The last etiological factor to consider was that of season, and sequelae were very largely a question of season. From February to the end of April, 5 cases occurred. From May to the end of July only 2 were noticed, one of which was definitely septic in origin. During September, October, and November, 3 cases occurred, and from the middle of December to the end of the following February no less than 11 cases, a state of affairs that was not stemmed even by the total abandonment of ether. The writer did not think that this epidemic was due to supplies of faulty anaesthetic drugs, but to the influence of the season on men debilitated by the hot summer through which they had previously served. He felt strongly that operation should only be undertaken in cases suffering from recent catarrhal infection when the emergency was great, and that all cases should as far as possible be submitted to a proper course of treatment before inhaling any anaesthetic. Colds in the head had formerly been taken much too lightly. Lastly, he thought that the time had now come when anaesthetists should refuse to take all the blame and odium of a post-operative pneumonia.

Dr. K. B. PINSON (Manchester) submitted a statistical survey of cases of which he had kept accurate records from January 1st, 1918, to June 30th, 1922, in order that an equal number of cold and warm months should be included in the period under review, and found two striking facts: (1) how

often patients with chest trouble came through the ordeal none the worse, and (2) how often, when complications occurred, they did so within twenty-four hours. His cases numbered 4,180, and serious complications occurred in 56 of these, 24 of pneumonia and 32 of bronchitis or minor complications, giving a total incidence of 1.34 per cent. He was willing to add one-third to these figures to allow for minor complications which had been missed and so to bring up the incidence to 1.8 per cent. In these cases he thought that 10 per cent. could not in any way be considered due to the anaesthetic. The ratio of pneumonia to bronchitis was high, but this was due to the fact that no account was taken of cases in which the cough or tightness of the chest was trifling. The ratio would be altered considerably if these minor cases were taken into account.

Nature of operation: The longer operations showed the highest incidence and also those in which the peritoneal cavity was opened, for whereas 35 per cent. of cases were abdominal, 75 per cent. of chest complications occurred in abdominal cases. Operations with unfavourable prognosis in respect of complications were: umbilical herniae in stout patients, partial gastrectomy, and prostatectomy.

Length of operation: The average length of administration in these 56 cases was forty-seven minutes.

Sex: Male, 32; female, 24.

Age: An unduly high figure was noticeable for the decade 61 to 70 years.

Time of year: 26 occurred in the warm and 30 in the cold weather.

Condition of patient: The results here were interesting, for it appeared that of the 56 cases, 4 occurred in the winter of 1919, when there was much bronchitis and influenza pneumonia about, 17 were coughing or had bronchitis or a cold or were asthmatic at the time of operation, or had had pneumonia a little time before. In addition, 9 were in poor condition due to alcohol, jaundice, debility, etc. Of the 24 pneumonia cases 10 had definite chest trouble, while 2 of these had had previous pneumonia. Ten of the pneumonia cases died, and of these 9 died from the lung condition; in other words, 9 out of 4,180, or 0.215 per cent. Of these 9 deaths he believed that 4 were due to the anaesthetic mainly. One had had a spinal anaesthetic, and another had only been given gas and oxygen.

He believed that the following conclusions were justifiable:

(1) A most important factor in obtaining a good recovery was the judicious choice of the agent and method used. (2) Any method of giving ether which involved rebreathing or caused deep breathing at any stage was to be avoided, since prolonged panting, coupled often with previous morphinization, tends to leave the patient in a torpid state, almost apnoeic, and liable so to infection of the lung. For this reason, after using it for a year in all cases, he had now given up prolonged administration of gas and oxygen except in those cases in which he had reason to expect that no ether would have to be added. The source of ether in all the cases analysed was his "bomb" apparatus.

Dr. H. PINTO-LEITE (London) stated that as the result of his experience in hospital practice he had come to the conclusion that sufficient attention was not paid to conditions of oral sepsis prior to operation. The services of the dental surgeon should be requisitioned in ordinary cases prior to operation and not, as was so frequently the case, only after operation. He also mentioned a case from his practice which ended fatally after the administration of rectal oil-ether given in the usually recommended dosage and by the usual method. The patient remained comatose after operation, and eventually died in bed some six hours later. No post-mortem examination could be obtained, so that the exact cause of death was not elicited. He was inclined to think that this rapid death was probably due to cardiac failure from shock rather than to a broncho-pulmonary condition. The operation had been undertaken for the excision of a lupoid ulcer of the face. Haemorrhage had been severe but not markedly excessive, and the patient had been in an anaemic and debilitated condition for some considerable time.

Dr. H. P. FAIRLIE (Glasgow), commenting on the previous speaker's conclusions in the case cited by him, considered that the rapidity of the onset of serious symptoms in this case, and its ultimate fatal conclusion in such a short time, did not rule out oedema of the lungs. He quoted a case of intravenous ether administration to a lad of 15 for hernia, in which 1½ pints of saline solution containing 5 per cent. ether

was administered. Within one hour after the administration had ceased he was called to see the patient, who was gravely ill with all the symptoms of oedema of the lungs—expectoration of frothy mucus in large quantity, laboured breathing, and intense cyanosis. The condition remained so for four to five hours and then began to clear up in response to free bleeding and continuous administration of oxygen.

Dr. W. BARRAS (Glasgow) submitted the results of 1,081 anaesthetics on male adults who had served in the army. Fallacies due to sex and age were thus omitted. The vast majority were heavy smokers and many were used to liberal supplies of alcohol. In most cases the mouth and teeth showed evidence of gross sepsis and a large number gave a history of treatment for previous lung affections. The patients were anaesthetized in a war-time structure which compared unfavourably with the usual civil hospital. Each was given 1/100 grain atropine and 1/6 grain morphine about thirty minutes prior to operation; induction was by C_2E_2 mixture followed by warm ether vapour from a Shipway's apparatus. Oxygen was frequently given in addition. In the series 386, or 35 per cent., had had previous chest trouble, whereas only 40, or 3.7 per cent., developed any bronchopulmonary complication after operation. The morbidity rate was 3.7 per cent., as follows: bronchitis 36 cases (3.3 per cent.), pleurisy 2 cases (0.2 per cent.), pneumonia 2 cases (0.2 per cent.). The mortality rate was nil. There were no cases of oedema, embolus, infarction, or abscess formation. Dividing the operations into groups, there were 52 head cases, of which 32 were for bone grafting, the rest for removal of foreign bodies, painful sears, etc. One case of pleurisy occurred in this group, the pleurisy occurring in the side from which a rib had been removed to form a graft. The average duration of anaesthesia was forty-five minutes. In the group for nerve sutures and repairs, 172 cases were dealt with, the anaesthetic average being thirty-five minutes. Bronchitis occurred in 4 cases. In the groups for bone grafting, plating, etc., 77 cases showed 5 cases of bronchitis after an average anaesthetic duration of eighty minutes. The abdominal group showed 63 cases with forty-five minutes' average duration of anaesthesia, resulting in 6 cases of bronchitis, 1 of pleurisy, and 1 of pneumonia; the pleurisy case suffered from subdiaphragmatic and liver abscesses. A miscellaneous group of 717 cases with an anaesthetic duration averaging forty minutes yielded 21 cases of bronchitis and 1 case of pleurisy and pneumonia. The latter case followed removal of ribs to facilitate drainage of a chronic empyema. The most striking feature of the statistics was the heavy incidence of complications in the abdominal group out of such a low morbidity rate.

This he attributed to several apparently trivial points—for instance, pain on coughing, dorsal decubitis with tendency to hypostatic congestion as a result, limited diaphragmatic movement resulting from pain and bandaging, with lessened pulmonary ventilation, and lastly, morphine and atropine exhibited freely after operation, reducing cough and favouring accumulation of secretion. He quoted a communication to the BRITISH MEDICAL JOURNAL (June 10th, 1922) from Mr. D. P. D. Wilkie of Edinburgh on the frequency of lung complications in persons suffering from inflammatory affections of the gall bladder and ducts, which would probably have been attributed to the anaesthetic, especially if ether had been used, had not a careful examination been made prior to operation. In conclusion, he stated that he believed "aspiration pneumonia" was an extremely rare sequela resulting from sucking gross septic matter into the air passages. His view was supported by his figures when it was remembered that most of his cases presented gross oral sepsis. He doubted whether chemical or mechanical irritation from anaesthetic vapours played much part in the etiology of post-anaesthetic complications. He believed that many factors were at work simultaneously, and that the anaesthetic vapour favoured complications by reducing the opsonic index of the blood, with consequent growth and multiplication of the causal organisms present in 60 per cent. of normal throats.

Dr. W. STIRK ADAMS (Birmingham), speaking as a member of the house staff of the Birmingham General Hospital, said that his work last winter in the general surgical wards brought him into close contact with the clinical side of the question. His limited experience led him to suspect that many cases of post-operative pneumonia were really cases of lung collapse, as in the course of six months out of 12 severe unexpected

post-anaesthetic lung complications, 3 were cases of massive collapse, and in 3 others this condition was strongly suspected but could not be proved. His first case of this nature, a very typical one, was the one of G. W., a healthy man, aged 20, who had a radical cure for right inguinal hernia performed. Thirty-six hours later he woke from sleep distressed and coughing, and from his general condition, and physical signs in the right base, lobar pneumonia was diagnosed, but to the speaker's surprise it was later established that a massive collapse of the lower lobe of the right lung had taken place. In collecting statistics of chest complications he found that the only reliable records were the *post-mortem* reports and the records of pulse respiration and temperature, especially when taken four-hourly during the critical period. Both in preventing and treating these cases he would suggest the extended use of atropine after anaesthesia, especially in the recovery stage where there was an excess of bronchial secretion. In this connexion the following case, in which 1/20 grain of atropine sulphate was given in the course of fourteen hours, seems worthy of mention. G. M., a male, aged 17, previously healthy, was operated upon for perforative appendicitis. Within twelve hours of operation he had signs of severe bronchitis, and four hours later was cyanosed with severe dyspnoea, and a respiratory rate of 44 a minute. Atropine, 1/100 grain, and oxygen were administered and temporary relief obtained, but three hours later his records were: temperature 104°, pulse rate 168, respirations 44; his condition seemed hopeless. The atropine was repeated, and again at further intervals, the fifth dose being given thirty hours after operation, after which he steadily improved and made an uneventful recovery. At no period were signs of atropine poisoning present nor were any signs of consolidation found in the lungs then or later. The speaker wished to thank Mr. Seymour Barling for permission to publish the notes of the cases cited.

DIFFERENT EFFECTS PRODUCED BY EXPOSING TISSUES TO VARIOUS CONCENTRATIONS OF ANAESTHETIC VAPOUR.

BY

A. L. FLEMMING, M.B., Ch.B., M.R.C.S., L.R.C.P.,
Bristol.

My excuse for addressing you is that I feel that, although remarkable improvements have been made in anaesthesia during the past twenty years, we can hardly claim that the ideal drug or method of administration has as yet been discovered. What form such an ideal anaesthetic, if it ever arrives, will take it seems impossible to predict; but whether a gas, an electric current, or a hypodermic injection, it will have to be so innocuous and so simple to administer that the personal factor can be eliminated and the skilled administrator dispensed with. The surgeon, in fact, will act as his own anaesthetist, and instead of pneumonia and bronchitis, pulmonary embolism and infarct will alone exercise his mind. The most likely place in which such an invention might originate is in one of the scientific departments of a university, but there seems to be a danger that such a discovery, if made, might be lost sight of owing to a want of interdepartmental co-operation.

The study of anaesthesia has been shown by Claude Bernard¹ to be within the province of all engaged in work on living organisms, since all such organisms are susceptible to anaesthesia, and the subject may therefore justly claim the attention of the physiologist, chemist, biochemist, zoologist, botanist, and physicist. As a result of the interchange of knowledge, we have seen magnesium sulphate, originally used by biologists for anaesthetizing marine animals, employed by Meltzer for producing spinal analgesia, and subsequently by others in synergic anaesthesia. Chloroform was suggested by a chemist, and, because its value was recognized, adopted at once. Nitrous oxide was suggested by

neglected for fifty years for want of this oblivion ought surely to be made impossible. Again, we have Vernet pointing out the close association which exists between certain electric phenomena and anaesthesia, and one wonders whether Le Duc's² electric anaesthesia might not be rendered practicable if scientific knowledge were brought to bear on the technique.

As to whether experiments with anaesthetics on lower organisms have any bearing upon our own work or teaching, it may be claimed that there are many factors common to

both cases. For instance, as correct dosage is of paramount importance in our case, so in the case of some of the lower organisms there is only a very narrow margin between the concentrations necessary to produce a reversible arrest of functions on the one hand, and to cause an irreversible arrest, or death, on the other. As an example, the *chlamydomonas*, a free-swimming vegetable cell, may be taken; 0.1 per cent. solution of chloroform stops movement, and after one minute in contact causes death, whereas 0.8 per cent. ether solution stops movements and recovery of most takes place after five minutes' contact; ether therefore proves more reversible than chloroform. My experiments were interfered with by the swarming of the *chlamydomonas* coming to an end. This organism was used in Harvey's experiments.

There is with most organisms a wonderful uniformity in the way their functions are in turn stimulated, retarded, arrested, and destroyed by increasing concentrations of ether or chloroform, and my few experiments have suggested a greater reversibility with ether than with chloroform. Stimulation is difficult to explain and to reconcile with theories as to the way in which anaesthetics act. I have failed to elicit a stimulation stage in the anaesthetizing of yeasts and seeds, but one significant direction in which stimulation can be shown to occur is in phagocytosis, as noted by Hamburger.³ In some opsonic index counts made for me some years ago, before and after ether anaesthesia had been induced, there was increase in the latter case varying from 0.2 to 0.4; this was also the case in an opsonic index count which a pathologist kindly made for me in an etherized patient recently. If small doses of ether can be shown to raise the patient's resistance to such organisms as the tubercle bacillus, we may find some justification for the employment of ether as a curative agent in phthisis as suggested by Dr. Hodgson⁴ in 1909.

Clinically we may not uncommonly see "chesty" conditions improve after operation, the credit being attributed, generally with justice, to the surgical procedure, but in what measure our anaesthetic should share in the credit it is difficult to say. The fact that practically every sort of living tissue is susceptible to the action of anaesthetics must make it difficult for scientific investigators to choose the most profitable point at which to attack this mysterious subject. But the more one considers the results of researches in anaesthesia, the more one realizes that our present drugs, if used in high concentration or over prolonged periods of time, produce a toxic effect and tend to depress vitality to such an extent that it is our bounden duty to make an art of employing the minimal dosage which is compatible with the surgery in hand. The dosage we can control, and the surgeon can be relied upon to limit the time of exposure. Complete reversibility is our first care, and the drug, or method, which offers us the widest interval between reversible and irreversible arrest of activity in our patient is the anaesthetic of choice.

It is in working along some such lines as these that I think our lay colleagues may most likely help us in our search for an ideal. Many experiments on lower organisms suggest that chloroform is more toxic than ether. For example, ciliary movement of the buccal membrane of the frog recovers more quickly after ether than after chloroform. In free-swimming protozoa which move by cilia the cessation of movement caused by ether is often temporary, whereas that produced by chloroform is generally permanent and accompanied by dissolution of the organism with rupture of the cell wall. This destructive effect of chloroform and ether upon plasma membrane is seen also in haemolysis of blood and in prevention of osmosis in the dandelion stem, or by loss of colour by beetroot when placed in water after being exposed to ether or chloroform.

I do not propose to tire you with details of experiments and accounts of failures, but I should like to suggest that regular and exhaustive research ought to be undertaken with a view to finding some innocuous and yet efficient drug or method, and that data gathered in experiments on lower organisms may be of great help in such research, which must be undertaken, not by tired anaesthetists in their recreation time, but by energetic scientists in their working hours.

MEDICAL, SURGICAL, OBSTETRICAL.

A COMPLICATED CASE OF INTUSSUSCEPTION.

Acute abdominal conditions in young children sometimes present very great difficulties, only being available. The

with which serious mistakes may be made.

A male child, aged 9 months, was seen at 3 a.m., help being sought by the parents because the patient seemed "very poorly" and unable to micturate. Examination revealed a large inguinal hernia together with a tight prepuce. The child looked ill and had a quickened pulse; the temperature was not raised and there had been no vomiting. Some blood had been noticed in the stools. The hernia was readily reduced by manipulation, and as a temporary measure the prepuce was stretched. Though it appeared that a sufficient reason had been found to account for the child's condition an uneasy feeling remained that this was not all, and the possibility of an intussusception could not be dismissed. When seen again a few hours later there was no improvement in the general condition; he appeared to be suffering from definite colicky pain and refused his food.

While we were discussing the case he passed a blood-stained stool, which to our minds settled the diagnosis. Immediate operation was decided upon. No tumour could be felt through the abdominal wall or on rectal examination even when the child was under the anaesthetic, nor could any emptiness be detected in the right iliac fossa.

On opening the abdomen a well-marked ileo-caecal intussusception was found and readily reduced. Complete recovery followed.

The question occurred to us whether the hernia had anything to do with the causation of the intussusception by setting up irregular peristalsis, etc.

TERMINAL HYPERPYREXIA.

The following note of an unusually high temperature, well authenticated, may be of sufficient interest to be recorded in the JOURNAL.

The patient was a man, aged 27, discharged from the army with hysteria and otitis media. There was a history of fairly frequent fits, hysterical in character, since November, 1919; also of otorrhoea intermittently since that date. He was admitted to hospital on August 10th, 1922, in a poor general condition with left otorrhoea. The region behind the left ear was red and tender, and fomentations were ordered; after this the condition subsided somewhat. During his stay in hospital the patient had about half a dozen hysterical fits. A radical mastoid operation was performed on September 27th. Two days later definite signs of cerebral abscess appeared, and despite all efforts death ensued the next day.

The interesting point in the case is the unusually high temperature registered on the last day of life:—6 a.m.: Pulse 68; axillary temperature 101.2° F. 7.30 a.m.: Pulse 100; axillary temperature 101.4° F. 10 a.m.: Pulse uncountable; axillary temperature 108.6° F. The latter temperature being maintained to the end, fifteen minutes later.

There was no doubt about the temperature, different thermometers being employed and the temperature readings taken personally. As these readings were taken in the axilla it is probable that the mouth and rectal temperatures were near 110° F.

A. MASSEY, M.B., D.P.H.

This high temperature of 108.6° F. in the axilla was confirmed by me at the time with my own thermometer.

Leeds.

H. S. CARTER, M.D.

In December, 1921, there were 47 lepers in Sardinia, aged from 17 to 72, 24 of whom were males and 23 females. Eight were of the tubercular variety, 26 of the nervous, and 13 of the mixed.

A SPECIAL course in orthopaedics will be given by Dr. Calot from January 2nd to 22nd, 1923, at his clinic, 69, Quai d'Orsay, Paris. The course will include such instruction in orthopaedics as is indispensable to medical practitioners (on congenital dislocation of the hip, infantile paralysis, scoliosis, etc.), on the treatment of non-pulmonary tuberculosis, and on the practical treatment of fractures. Instruction will be given not only in French but in English and in Spanish. The fee is 150 francs; further information may be obtained from Dr. Collet, Clinique-Calot, 69, Quai d'Orsay, Paris.

British Medical Association.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

METROPOLITAN COUNTIES BRANCH: WILLESDEN DIVISION.

A MEETING of the Willesden Division of the British Medical Association was held on October 18th, with Dr. SKENE in the chair, when a paper was read by Mr. F. D. SANER.

The Chronic Abdomen.

Mr. SANER said that his object was to give a survey of some of the chronic disorders of digestion associated with abdominal pain. Although in the diagnosis and technique of treatment of such cases much progress had been made, there was still a marked divergence of opinion on the possible fundamental pathology, on which treatment must primarily depend, and also on the meaning of the various findings in the abdomen.

Three groups, as and operative findings: Class 1, in which the symptoms were mainly abdominal pain or discomfort, erratic and irregular in type, and in which no gross local lesion was discoverable. Class 2, in which a definite local lesion—for example, a gastric or duodenal ulcer, cholecystitis with or without gall stones, etc.—was present. Class 3, in which the symptoms were largely abdominal—namely, "indigestion" and "constipation"—but in addition marked changes were shown in the nervous and endocrine systems, with general signs of auto-intoxication.

In Class 1 the main symptoms were irregular abdominal pain, more or less associated with or excited by food, gradual in onset, but rarely with any direct causative factor. The symptoms were associated with a low position of the stomach and large bowel, with spasm or delay in sections of the tract, frequently with a mobile ascending colon and bands or kinks at certain points. The relation of these symptoms to the appendix was then considered; although the appendix was frequently diseased, that was only one among further changes in the intestinal tract. In such cases removal of the appendix was a sound procedure, as the foundations were laid for an acute process, but it was a limited measure. A further mechanical cause was discussed in the drag due to the dependent position of the stomach and intestines with special stress at certain fixed points; this drag, accentuated, perhaps, by external causes, produced neuro-muscular changes in the intestinal wall with consequent hyperexcitability or inertia. A large part was played in the production of this drag by the large bowel as a whole or by a mobile ascending colon with its pull on the abnormal mesentery. The relative value of surgical treatment in these conditions was also discussed.

Class 2 presented a definite gross lesion, probably partly infective or toxic, partly mechanical in origin, and the point was raised as to whether these cases were a further step in the evolution of Class 1 or a collateral manifestation of the same basic pathology. It was characterized by the typical pain, regular with periods of intermission, as contrasted with the pain of Class 1. In attempting to explain the causation of a chronic ulcer, the fact that almost always identical areas were involved pointed to a certain specificity on the part of the infective agent. With the object of defining the source of the infective factor, reference was made (1) to dental sepsis in general, (2) to the appendix, (3) to the end-results of intestinal stasis or altered bacteriology of the tract, and (4) to the action of infarction emboli of bacteria. The main difficulty in accepting these suggestions seemed to be the disproportion of cause and effect. In searching for a common predisposing cause, it was seen that the ulcer-bearing area corresponded to the area of constant mechanical strain. The operative treatment of the gross local lesion was discussed, and stress was laid on the importance of after-treatment.

The cases in Class 3 were grouped into various special departments according to their predominant symptom complex. The main abdominal symptoms were chiefly "chronic indigestion" and "constipation," while there was a general failure in the endocrine and nervous systems. The whole was regarded as a "deficiency" or "degenerative" disease, and, as a cause, the possibilities were discussed of chronic auto-intoxication from various sources, the heritage of tissues unable to deal with the stress of life in general, and the effects of toxins inherited from the parents.

In the discussion which followed the paper, Dr. SKENE, Dr. ANDERSON SMITH, Dr. TRAYLEN, and others took part, and Mr. SANER was afterwards accorded a hearty vote of thanks.

Reports of Societies.

THE PROGRESS OF SURGERY.

At the meeting of the Section of Surgery of the Royal Society of Medicine on November 1st Mr. JAMES BERRY, the incoming President, delivered an address on the progress of surgery, which was followed by a discussion.

Mr. BERRY said that it had fallen to his lot to witness during his surgical life the most wonderful progress that surgery had ever made in so short a time. As a student he just saw the termination of the pre-antiseptic days. Much of the progress which had been made in surgery was due to the application first of antiseptic and later of aseptic principles to the treatment of operation wounds. In his very early experience he remembered surgeons who wore frock coats at operations, and the more dirty and blood-splashed the coat the prouder its wearer seemed to be. He had seen a hospital surgeon stop in the middle of an operation to scratch his head; he had seen a surgeon put his hand in his pocket, take out his glasses, put them on, and continue the operation; he had seen a surgeon divide a ligature with his teeth when the scissors were not handy. It was not necessary to embark upon any eulogy of modern surgical triumphs, but he thought there was some danger to-day lest the ordinary surgeon be over-impressed by the brilliant results of a few outstanding masters, and imagine that he could do anything that they did. An extensive operation upon the brain, which might be a brilliant success in the hands of a Harvey Cushing, might result in terrible disaster in the hands of a surgeon not specially trained along this line, even though the same method of operation be followed in each case. At one period in his own surgical career he had the good fortune to be surgical registrar for five years at a large hospital, and to make large numbers of post-mortem examinations. The young surgeon could have no better training than that which was obtainable in the post of registrar if it involved, as it ought to do, the clinical observation of patients in the wards, the witnessing of all important operations, and the doing of post-mortem examinations. The modern practice of entrusting surgical necropsies to a non-practising pathologist was in some respects a retrograde step. Only assiduous attendance at hospitals enabled the young surgeon to acquire experience, especially in those operations which were undertaken when sepsis was already present, as in acute suppurative conditions of the abdomen. It was not so much a mere grounding in technique that was needed as the experience and knowledge of what to do and what not to do. His own opinion was that operations for appendicitis were performed rather too frequently at the present day, but he knew of no rule as to when such an operation should be undertaken, and each case of appendicitis must be dealt with on its merits, according to the judgement of the operator. With peritonitis he thought it was generally useless to attempt thorough cleansing of the peritoneal cavity, and he described cases in support of this view. The peritoneum itself had enormous powers of repair; it should be interfered with as little as possible. He was reminded of what one of his former teachers, the present President of the Royal College of Surgeons, used to say: "Think, before you do an operation, what is likely to be the course of the disease if the case is not operated on, and what is likely to be the effect of your operation." Cases were often undertaken without serious consideration of this important point. It was frequently stated that the modern custom of operating freely for acute appendicitis had resulted in great saving of life. If this was so, surely deaths from appendicitis would be far less frequent now than they used to be unless one could assume, as some boldly did, that the disease itself had become more frequent. Of this there was no clear evidence. He had compiled from the Registrar-General's returns the figures for the deaths from appendicitis and perityphlitis in England and Wales for certain periods as follows:

Deaths from Appendicitis and Perityphlitis.

1901-05	8,291
1906-10	10,836
1911-15	12,740
1916-20	12,418

These statistics, however, needed correction by reference to other conditions, among which, especially in the early periods,

appendicitis might have been ranked, and to the totals for all diseases of the digestive system:

Total Deaths (England and Wales).

	Peritonitis (non- puerperal).	Intestinal Obstruction.	Gastric Ulcer.	All Diseases of the Digestive System.
1901-05 ...	5,460	12,759	8,386	145,320
1906-10 ...	3,421	12,900	8,786	128,334
1911-15 ..	2,740	12,632	9,374	119,759
1916-20 ...	2,155	12,977	9,650	123,101

More statistics, however, were apt to be misleading. He brought forward all these figures rather as food for reflection than with the intention of drawing any definite conclusions from them.

No doubt the war (Mr. Berry continued) in many directions produced great advances in surgery, but in one respect it brought a disadvantage. Large and dangerous operations were now being undertaken by many practitioners whose chief experience had been of military injuries, inflicted for the most part upon young and healthy men. Such experience did not give the necessary qualification for dealing with, say, tumours of all kinds, diseases of the stomach, colon, prostate, and so on. There was too much inclination to imagine that operative surgery was a very easy matter, and that the young surgeon had only to exercise surgical cleanliness and then could proceed to do with impunity anything that he had seen his seniors do. Later on he was likely to find that in actual practice this was not so easy. Mr. Berry gave instances, some tragic and others amusing, of the mistakes he had seen made by men who strayed into fields of practice which did not belong to them. One useful reflection was that they became wiser through seeing the errors of their predecessors. His own favourite definition of a good surgeon was "one who always knows when to put in and when to take out a drainage tube." In conclusion he quoted a description of a surgeon recently written by Sir Frederick Treves, who likened the knowledge which the surgeon must have of the human body to the knowledge which the forester must have of his wood.

Sir JOHN BLAND-SUTTON said he had been specially interested in what Mr. Berry said about the inexperienced man in general practice undertaking operations which sometimes caused surgeons of experience to quail. Forty years ago there was not a book entirely devoted to the subject of operations in general or to special surgery. To-day such books were plentiful, and commanded a ready sale, but, of course, it was a poor way of learning how to perform radical operations by studying them from a book, no matter how well written or lavishly illustrated. The modern treatment of wounds had changed the qualities expected of a good surgeon. In pre-antiseptic days the qualities of a good surgeon were a thorough knowledge of human anatomy, courage, and manual dexterity. Since the introduction of antiseptic and aseptic methods it was a truism that, although the brilliant surgeon might attain fairly good results, he was often beaten by a slow and sometimes clumsy colleague because the latter was more careful with his asepsis. It had been said that the man who now practised as a surgeon might achieve great success even if he had a shaky hand, but that the man with the shaky mind was hopeless. During the last twenty-five years the number of operations done in hospitals had increased fourfold, and the surgical staffs of hospitals had also largely been increased. The amount of operating done in a hospital was so great that the surgeon found it difficult to do all the operations which came to him in his wards, and if he had a capable house-surgeon he allotted a fair number of the lesser operations to him. There were more house-surgeons training in London than could possibly receive appointments on the staffs of hospitals either in London or the provinces, and many of them would go into general practice, where they naturally wished to do such operations as were within their power. It was well understood that a successful operation upon a popular person might make a great reputation, but, on the other hand, in a small community an unsuccessful operation upon a poor person might ruin a practice. In small towns or groups of towns a team arrangement was coming into being; one member of the team would be a good anaesthetist, another would have surgical proclivities, a third would be well trained in

gynaecology, and a fourth in laryngology; and with the help of a well-trained nurse a nursing home would be started in which these men would work together and sometimes make a good living by doing all the surgery without calling in any outsiders. But such practitioners must remember that when they ventured upon an unusual operation, or even an operation which they thought straightforward, they might find themselves faced with difficulties which would try the boldest and most experienced surgeon. Unless a man was going to do a certain amount of minor surgery he might find it rather difficult to make ends meet, but he should keep well in mind the warning that many minor operations ended in major disasters, and that this might happen not only to beginners but to surgeons of experience and men of renown.

Sir W. ARNOLD LANE said that while occasional surgical failures might not be noticed in London, it was different in smaller places, where they might seriously affect a man's practice. A famous American surgeon once said to him that he was very careful about his mortality, because "if I send one of my patients home in a box to his particular place, that place becomes a dry spot for me." It was possibly a good thing to see an operation badly or imperfectly performed. A good deal more was learnt from such an operation than from one that was perfectly done. Once when some American surgeons were over here they visited a hospital, and one of them was seen to be taking notes furiously. His colleagues, who did not think much of the operation, asked him why he was taking such careful notes, and he replied, "I was putting down all the things one should not do." The general practitioner in this country laboured under some disadvantage as compared with his American colleague. An American doctor, after qualification, put his money into travel. He went round and saw the best surgeons in the world—Paris, Vienna, Berlin, and his own Rochester. The other day the speaker was in Germany, talking to some American surgeons, and trying to get them to come to England. "But," they said, "we live for next to nothing here, and we get intensive courses, beginning at seven in the morning and going straight on until five. Will your people get up before seven o'clock in the morning to teach us?" And, of course, when the American doctor went back home there was a description in his local paper of the places he had been to, his appreciation of the men he had seen, and perhaps, also, their appreciation of him! Nevertheless, the speaker fancied that the English surgeon and general practitioner, however difficult his process of evolution, would come out in the end equal to anybody else in the world.

Professor A. W. SMITH said that he had been hoping to hear from Mr. Berry of operations which had been in great vogue and were now out of date. Such operations when they were introduced were always backed up in the periodicals by a series of statistics, how obtained he did not know, and yet afterwards the operation went entirely out of vogue. He passed on to speak of the value of the follow-up system in estimating surgical results—not merely the results from the point of view of the immediate danger of the operation, but from that of any permanent damage or impairment which might result. In saying this he was referring to such quite common operations as those for hernia, hydrocele, haemorrhoids, varicose veins, and so forth. There were often little troubles or disabilities which resulted owing to an imperfect operation or to some damage which was done and need not have been done at the time it was performed. As to the need for training surgeons, he was inclined to think that this was not sufficiently appreciated in London, or in big provincial towns, where the highest surgical skill was always available. But men went out from the schools of this country into all the world, and had to perform operations which there was no one else to do. In India he had seen something of the work of the Indian Medical Service, and he was filled with admiration for the way in which its members tackled, and tackled well, all sorts of jobs. But he still felt that for the men who went out into distant portions of the empire more ought to be done in the way of special training for the great amount of surgical work which called for their attention. He appealed also to writers of textbooks to describe operations as far as possible in such a way that a person reading the description could perform the operation.

Sir D'ARCY POWER said that so far as he had had experience of the surgical work of general practitioners he had no fault to find with the way they did it, but he thought they were not always as careful as they should be in making their diagnosis beforehand. Dr. F. W. COLLINGWOOD thought that there was not sufficient trouble taken in this country to

furnish opportunities for practical experience in surgery to men who would go out as general practitioners and would of necessity be called upon in emergency to do operations when to call in a surgical specialist was out of the question.

THE ANAESTHETIZATION OF PATIENTS FOR CLASSICAL CAESAREAN SECTION.

At the meeting of the Section of Anaesthetics, Royal Society of Medicine, held on November 3rd, Dr. HENRIET SPENCER opened a discussion on "The anaesthetization of patients for the classical Caesarean section." His paper is printed in full at page 905.

The President, Dr. A. L. FLEMING, read letters contributing to the discussion from Dr. Miles Phillips, who stated that for some years he had used ether and had had no trouble from asphyxia of the child, whereas when he used chloroform the trouble was that the child would not cry; and from Dr. Goodman Levy, who referred to the immunity from chloroform syncope of women in labour—an immunity with which, he believed, the peculiar temperament of the pregnant woman had something to do.

Dr. LIONEL SMITH raised the question whether deep anaesthesia throughout labour was really harmful to the child. He had seen hundreds of ordinary labours under deep anaesthesia, and the children, often after prolonged manipulation, had been born alive and able to breathe. It was otherwise very often with the child delivered by Caesarean section, because that child had not gone through the necessary process which fitted it for life in the open. Dr. A. B. KINGSMAN agreed with Dr. Spencer's method; he had done about thirty cases by this method, and they had given him no anxiety—the child seemed to breathe almost immediately. Dr. H. W. FEATHERSTONE supported the open-ether method, regarding this as preferable for the mother, and he had never failed to induce the child to breathe, though he admitted that many of the children suffered to some extent from asphyxia. With regard to the previous administration of drugs, he did not quite see why atropine should have any ill effect, though he agreed that morphine was to be avoided. His practice usually was to induce anaesthesia by means of pure ethyl chlorido with the open mask, and then to carry on with ether in the ordinary way. He had carefully noted blood pressures, and had found no very great drop at any stage in the operation. Dr. E. W. GANDY said that experiments on animals, supported by evidence from observations on the human, suggested that the child *in utero* did not stand chloroform so well as ether. Dr. H. J. SHIRLEY agreed with Dr. Spencer's method, and referred to the desirability of adopting inhalation rather than spinal anaesthesia because of the importance of eliminating psychic shock. Dr. A. S. DALY, on the other hand, totally disagreed with Dr. Spencer. In his own resident days the patient upon whom a Caesarean section was done was always given chloroform, and when this was done there was the greatest difficulty in getting the babies to recover and to breathe well. But with open ether there was a great improvement in this respect: there was not the same trouble with the children. He agreed as to the objections to spinal anaesthesia, one of the difficulties of which, in the case of the pregnant woman, was to get the position in which to give the injection. Dr. F. W. LONGMURST said that his experience was that asphyxiation had to be dealt with far more frequently in ordinary deliveries, instrumental or otherwise, than in Caesarean section. Whether there was some medullary injury in these so-called normal deliveries he did not know. In ordinary Caesarean sections he had always induced or half induced anaesthesia with chloroform, and carried on with a mixture of chloroform and ether, probably adding the ether rather later when the mother was well under. He did not recall any trouble with the respiration of the child afterwards.

Dr. J. BLONFIELD said that Dr. Spencer's experience did not tally with his own as regards the effect on the child. He asked whether Dr. Spencer had noticed anything to suggest that the effect on the child was due to ether in the respiratory passages. Was there any mucus in those passages? In his own experience of Caesarean section a mixture of chloroform and ether was given, and he had seen nothing of asphyxiated infants. Dr. E. G. BOYLE was rather surprised to hear that the children who were delivered by Caesarean section when the mother was given ether were asphyxiated, and he was curious to learn the reason why. He would have thought it safer to have given ether than to have given chloroform. He had an idea that a good many of the

deaths in childbirth were due to chloroform. He gave an account of the gas and oxygen method, and of its use in Canada, where he had seen and appreciated it. Dr. W. J. BLONFIELD said that the method of other administration was not for the results which Dr. Spencer had said whether he had found asphyxia caused more frequently by the open than by the closed method of giving ether. Dr. F. E. SURWAY thought it a pity that anything should be laid down as a routine method when conditions so various called for methods adaptable to each particular case. Dr. G. F. HADFIELD's experience was that the child breathed very much better if ether rather than chloroform were given throughout. In the ordinary confinement ether was given very satisfactorily indeed. Dr. F. W. COLLINGWOOD said that he had found the effects of chloroform on the child to be such that he took to open ether, first giving twenty drops of chloroform to dull the sensibility of the mother, and then continuing with the ether.

Dr. HENRIET SPENCER, in reply to the discussion, said that if more of his obstetric colleagues had been present he would have received a larger volume of support in favour of the method he had advocated, because their experience was that children were frequently asphyxiated under the ordinary administration of ether. With chloroform administered as he administered it the child was never asphyxiated, though he agreed that the governing factor was not chloroform, but chloroform plus α —moaning by α the expert administrator. As to the previous administration of drugs, he was not very fond of atropine, though he did not know that there was any particular objection to its use. Morphine certainly should not be used, as it introduced an element of danger for the child. In reply to Dr. Blomfield, he did not think that there was any mucus in the air passages of the asphyxiated child. The child was simply poisoned by the ether given in too large quantities. He thought it quite possible that the gas and oxygen method was useful, but no one in this country had had much experience of it, and his own preference was for a quieter method, for it was very important that the patient should not strain. Altogether he was not satisfied with the discussion, because he had not been told definitely whether a patient ran any appreciable risk from having chloroform given for six minutes. It ought to be remembered that he was not advocating any prolonged administration of chloroform; some speakers, in comparing the advantages of different methods, had appeared to suppose that his method implied an indefinite chloroforming. This was not the case at all. He did not think that there was any risk, if the chloroform was administered by an expert, but if anaesthetists declared otherwise he would reconsider his position. As it was, he felt that his experience justified him in going on with his method.

Dr. C. W. DUNN of Philadelphia, in reply to a remark in Dr. Spencer's paper with regard to the employment of nurses to give anaesthetics in the United States, said that the reason for this was that at present in America there was a great shortage of doctors. The medical students now entering were only 50 per cent. of the number who entered in 1912, and yet during the last ten years the population had greatly increased. The decrease in the number of men training for medicine was due to the prolonged course—now six years, and possibly soon to be eight—necessary for obtaining a medical degree. In those circumstances it had been necessary to train nurses to give anaesthetics, but they did so under the supervision of medical men.

TREATMENT OF BONE AND JOINT TUBERCULOSIS.

The second meeting of the Sheffield Medico-Chirurgical Society this session, with the President, Dr. RUPERT HALLAM, in the chair, was held on October 26th at the King Edward VII Hospital, Sheffield, a hospital devoted to the treatment of bone and joint tuberculosis in children. The medical superintendent, Dr. C. LEE PATTISON, demonstrated some of the cases in the hospital, and showed the methods he adopted and the apparatus he used in the treatment of various types of joint and bone tuberculosis; the special plaster room was visited. Dr. Lee Pattison then read a paper on "The local treatment of acute tuberculous disease of the hip-joint and vertebrae." He laid emphasis on the fact that tuberculous joint disease was merely one local manifestation of a general disease, and deprecated the radical measures that had been adopted formerly in the treatment of these

conditions. He was an ardent upholder of the conservative methods as laid down by Ménard, Calvé, and Calot in France and by Sir Henry Gauvain in this country. Complete immobilization and the prevention of muscular spasm were the essentials in treatment, and on these attention should be concentrated. In the hip-joint, in addition to extension in the axis of the limb, Dr. Pattison had found lateral extension in the axis of the femoral neck very useful. When the spasm of the muscles had diminished and the limb was in good position and there was no sign of abscess formation immobilization was maintained best by fixation of the limb in a plaster-of-Paris splint. In the vertebrae, tissue destruction and the effects of muscular spasm in producing a kyphotic deformity might be minimized by fixing the patient in a recumbent position with a pad exactly under the spinous processes of the affected vertebrae. Aids in the carrying out of this treatment were obtained by utilizing some type of "swinging back door" or the "wheelbarrow" splints. Extensions might be fixed to the head or lower limbs if necessary. He thought that Albee's operation was justifiable in adults only where time was absolutely essential, and was definitely contraindicated in children. Abscesses should be treated by aspiration, repeated many times when necessary; the details of the technique of the operation were described and the advantages of the various modifying liquids enumerated.

The President, Mr. J. B. FERGUSON WILSON, Mr. E. FINCH, Mr. MILES PHILLIPS, and others took part in the discussion which followed. Dr. LEE PATTISON was warmly congratulated on the results of the procedures he adopted, as was evidenced by the excellent appearance and wonderful vitality of the patients undergoing treatment.

TREATMENT OF DISSEMINATED SCLEROSIS.

The first ordinary meeting of the new session of the Liverpool Medical Institution was held on October 26th, with the President, Dr. J. HILL ABRAHAM, in the chair.

Dr. W. JOHNSON, in a note on drug therapy in disseminated sclerosis, dwelt on the necessity of treatment in the early stage of the disease, before the nervous system had become riddled with plaques of sclerosis. He reviewed briefly the symptoms which usually occur first, and said that frequently these symptoms were regarded as hysterical. A not uncommon history was that of a slight pyrexial attack followed by vague paresis, paraesthesia, temporary diplopia, or misty vision. Subsequently marked improvement occurred, until a new attack followed with a fresh exacerbation of symptoms. Such a series of remissions in the course of a progressive nervous disorder was almost diagnostic of disseminated sclerosis. Continuing, Dr. Johnson stated that during the past two years ten early cases of the disease had been treated with intravenous injections of novarsenobillon. An initial course of six weekly injections (0.15, 0.3, 0.45, 0.45, 0.6, and 0.6 gram) was given. This was repeated six months later. In between the two courses, and subsequently for a year, liquor arsenicalis was given by the mouth. Such a line of treatment has seemed to stay the progress of the disease, but observation over a longer period is necessary before any conclusions can be drawn. Dr. Johnson added that the first suggestion for this form of treatment came from Dr. Farquhar Buzzard.

Dr. T. R. GLYNN remarked that it was satisfactory to learn that there was a prospect of doing something by treatment for that hopeless disease disseminated sclerosis. Unfortunately, it appeared that treatment to be successful must be adopted in the early febrile stage. The recognition of the affection in that stage must be difficult and depended on the ability of the general practitioner rather than on that of the specialist or physician, who generally meet with disseminated sclerosis when more advanced.

Dr. JOHN OWEN referred to the importance of and difficulties attending early diagnosis. He read a communication from Dr. RANSOME, who was unable to attend the meeting. Dr. Ransome had treated 26 cases of disseminated sclerosis of a standing ranging from two to five years and over. He employed silver salvarsan intravenously—a total of 664 injections. His results were as follows: 4 were much improved, 8 no change, 2 died of intercurrent disease, 1 died of cancer. His course of treatment extended over two years.

Dr. A. DOUGLAS BIGLAND stated that he had not seen the early cases described by Dr. Johnson. The only early symptoms usually referred to by patients were temporary diplopia, temporary loss of vision, and precipitate micturition. He

agreed that early diagnosis was of the utmost importance and emphasized the value of spinal fluid examinations. A motic or parietic curve with Lange's gold-sol test, together with a negative Wassermann reaction, was very suggestive of disseminated sclerosis.

Sacro-iliac Tuberculosis.

Mr. H. C. W. NUTTALL read a paper on tuberculosis of the sacro-iliac joint, in which he reviewed the literature of the subject and gave records of nine cases, for eight of which he was indebted to Professor Thelwall Thomas. Mr. Nuttall considered that the treatment advised in most textbooks was often not radical enough, and that Piqué's operation was suitable in many cases. He discussed the anatomy and pathology of the joint, and expressed the view that this supported the necessity for more radical methods. He reviewed the clinical facts and the differential diagnosis of the condition, and described in detail M. Piqué's technique, illustrating this by lantern slides.

Mr. T. P. McMURRAY stated that in his opinion the operation of Piqué was a great advance on those previously employed and led to a much greater chance of cure. He had operated on six of these cases by a modification of this method, which he thought was a decided improvement in method. This modification consisted in the turning over of a hinged bone flap from the back of the ilium across the gap left after excision of the joint. This led to bony union and increased the stability of the pelvis.

Recent Work in Palaeontology.

Dr. J. C. M. GIVEN, in a paper on recent discoveries in palaeontology, gave an account of some of the recent work that has been done in human palaeontology. He discussed the difficulties felt by some authorities in the reconstructing of Pittdown man, especially the combination of the marked chimpanzee-like inferior maxilla with a human cranium. He then described the Rhodesian skull, and illustrated by lantern slides. He remarked that the geological evidence did not point to extreme antiquity, but its form was very primitive and ape-like, and it presented in a marked degree some of the characters of the Neanderthal race. He then pointed out the supposed evidence of mastoid disease and the fact that this was denied by Elliot Smith to be *ante mortem*. Dr. Given concluded by discussing the Nebraska tooth, with the hypothetical new genus of homo, built on its supposed human origin, and also alluded to its importance, if authentic, as throwing light on the early origin of man in America.

INCIDENTS OF OBSTETRICAL PRACTICE.

A MEETING of the North of England Obstetrical and Gynaecological Society was held at Liverpool on October 20th, with the President, Mr. HAROLD CLIFFORD, in the chair.

Dr. FLETCHER SHAW (Manchester) described a case of occlusion of the rectum following the administration of a simple enema.

The patient was a primigravida to whom the midwife administered a simple enema at the beginning of labour. There was some difficulty in inserting the nozzle and considerable pain was experienced as it was pushed in with force, with still greater pain when the enema was injected. Very soon afterwards the perineum became very swollen and red. At the end of twenty-four hours, when a doctor was called in, there was so much swelling that a vaginal examination could not be made, and the parts were so red that erysipelas was diagnosed. The patient was delivered in a side ward of St. Mary's Hospital, and then sent to the fever hospital with this diagnosis. She was later sent home, with the recto-vaginal septum completely sloughed away and a large sinus in the right ischio-rectal fossa. Eventually the rectum closed down to a mere band of fibrous tissue, and the patient is now condemned to a permanent colostomy opening. It seemed probable that the nozzle of the enema syringe was detained by a fold of rectal mucous membrane, and the force used in inserting it further pushed the nozzle through the mucous membrane so that part of the injection was given into the peri-aural tissues. This would account for the early swelling, the further swelling and redness being caused by infection of this area from the rectum.

Dr. LEITH MURRAY (Liverpool) reported a case of unsuspected pregnancy. He said that several cases of unsuspected pregnancy had been recently detailed in the *BRITISH MEDICAL JOURNAL*, and, in view of its medico-legal importance, it seemed advisable to record a case of that nature which had come within his own knowledge.

He was asked to see a young married woman, aged 24, in 1920, by Dr. A. C. Ransome of Birkenhead. Twenty-nine hours previously she had been delivered of a 6½ lb. child, apparently at term. She had been happily married for three years, and during most of that

time had lived abroad, where she developed enteric fever. As a result of this acute illness she lost 3 st. in weight, but during recent months was pleased to find that she was, as she thought, picking up. Her menses had always tended to be scanty and infrequent, and there was complete cessation for some time following the enteric fever. She gave, however, a very precise history of having had a more or less monthly loss throughout the whole of her nine months of pregnancy, of such duration and quantity as to lead her to believe that she was menstruating. She had had no vomiting, had felt no movements, and had no idea whatsoever that she was pregnant. Between the seventh and eighth months she announced to her mother that her abdomen was getting very big. Her mother promptly asked her whether she were pregnant, but on hearing of these "menstrual periods," and of the total absence of any other symptoms, told the daughter there could be nothing of the kind. For a few weeks before her return to Birkenhead she had been with her husband away on holiday, bathing, dancing, and golfing. Neither of them had any objection to parenthood, and, as they were well-to-do, there was no reason why arrangements should not have been made for the baby. She and her husband arrived in Birkenhead on the 27th of a certain month to be present at a celebration given by the husband's parents, and as many other members of the family had also arrived they had to be accommodated in a boarding house. While walking thither late in the evening of the 23th of the month she complained to her husband that she had eaten something at dinner which had disagreed with her, and the following morning, as she still had pains in her abdomen, her husband advised her to stay in bed whilst he proceeded to Liverpool on business. The abdominal pains increased in severity, and at 10.30 a.m. she discovered that delivery was imminent. She was unable to attract attention and delivered herself unaided at 11 a.m. The placenta was delivered normally, but there was considerable bleeding thereafter. My presence was necessitated by rather severe lacerations of the vagina, which were leading to continuous oozing. These were sutured under an anaesthetic and healed well. The child's palate was scored in several places by the mother's nails in her attempts to expedite delivery. It was noticeable that there were very few striae on the abdomen. The patient appeared to be rather big-boned but certainly not fat. Her height was about 5 ft. 6 in. She was a well-educated and intelligent girl, and her distress at the lack of provision for her offspring was very obvious.

Dr. LEITH MURRAY also narrated a case of simulated disease. The main interest in the case lay in the fact that a girl of 20 should have succeeded, by producing diapers artificially stained, in deceiving her mother, her doctor, and a consultant into believing that she was menstruating excessively.

She was brought to him in August, 1919, with the request that he should remove the uterus. Her periods, which began at the age of 15, were reported to be regular until she went to school at 16. Three months of amenorrhoea ensued, followed, the report went, by severe and prolonged periods ever since. For months at a time she was supposed to be only a few days free from loss in each month. She had been cured in April, 1919, without any improvement, and had been given thyroid extract, hamamelis, calcium lactate, and ergot. On examination she proved to be a slim little girl, rather pale than otherwise, but not excessively so. She was highly neurotic, and rectal examination, which showed a normal pelvis, was only made with extreme difficulty. As she was not bleeding on the day when seen, Dr. Murray asked for a diaper to be sent to him. This was received a fortnight later, and presented an appearance remarkably like menstrual staining. There was, however, no trace of blood detectable by the benzidine test. Two other specimens of blood passed into the chamber were received within a few days, and were sent for analysis. A report was received that both specimens were similar in composition, and undoubtedly consisted of urine to which some colouring matter analogous to cochineal had been artificially added. When challenged by her mother the patient admitted having on one occasion only used cochineal from the kitchen cupboard to colour the diaper. The last Dr. Murray heard of her was that her mother considered she had been very unkindly treated by him and was endeavouring to find someone who would remove the uterus.

A number of specimens were shown by Dr. BRIGGS, Dr. BURNS, Dr. DOUGAL, Dr. KING, and Dr. LEITH MURRAY.

MANCHESTER PATHOLOGICAL SOCIETY.

AN ordinary meeting of the Manchester Pathological Society was held in the reading room of the Manchester Medical Society's library on Wednesday, October 18th. The retiring President, Mr. J. HOWSON RAY, vacated the chair, which was taken by Professor SHAW DUNN.

Dr. DOUGAL showed a specimen of hydrometra from a case of congenital absence of the vagina. Tuberculous salpingitis was associated with the condition. Dr. DOUGAL showed, further, a chorion-epithelioma of the uterus, the third that had been recognized in Manchester since 1905.

Dr. DIBLE showed a case of a single canceroid tumour of the small intestine. The growth, which was of the size of a large pea, occurred in the ileum and was found at necropsy in a patient dying of pernicious anaemia. The tumour was infiltrating and histologically malignant. The source of such growths, which appear to be identical with the canceroid

tumour of the appendix, was discussed and the opinion expressed that the growth in this case was derived from intestinal mucosa and was analogous to the basal-celled carcinoma of the skin.

Dr. DIBLE also showed a case of x-ray epitheliomatous warts in a person who had been exposed to the Roentgen rays for twenty years. Well-marked hyperkeratotic nodules were present and also typical epithelioma. Attention was also drawn to the relative benignity of the tumour. Amputation of the affected fingers had been performed two years previously, and no recurrence had been noticed up to the present time.

Mr. GEOFFREY JEFFERSON read a short paper on distortions of the sella turcica in non-pituitary lesions. He showed some photographs of the floor of the third ventricle in posterior fossa tumours which had led to obstruction of the cerebro-spinal fluid pathway. He was also able to show the sella from one such case where the bulging floor of the third ventricle had opened up the diaphragma sellae and compressed the pituitary body. The interpretation of erosions of the dorsum sellae in the reading of x-ray plates was discussed, and the findings of Bacter and Dandy in this connexion in part confirmed. Destruction of the posterior clinoid processes and of the dorsum sellae did not, however, appear to be uniformly found in adult hydrocephalus.

Dr. RILEY exhibited a specimen of sarcoma of the kidney removed from a child by Mr. H. H. RAYNER. Dr. RILEY referred to Mr. JOHN FRASER's work on the renal sarcomata of infancy, and exhibited numerous sections from different parts of the tumour, demonstrating variations in histological pattern.

Mr. JOHN MORLEY described a cyst which he had fortuitously discovered free in the peritoneal cavity of a middle-aged man operated upon for acute appendicitis. This cyst contained clear fluid enveloped by a tough membrane, and its origin was not very certain. It had no attachments, and the view was put forward that it was a cyst of peritoneal development.

ON November 3rd a clinical meeting of the West London Medico-Chirurgical Society was held under the presidency of Dr. A. G. WELLS. Medical cases were shown by Drs. BURNFORD, BURRELL, CAPLAN, PENDRED, ROSS, and SAUNDERS. Mr. NEIL SINCLAIR and Mr. SIMMONDS showed surgical cases and Mr. MAINGOT showed a case for Mr. MCADAM ECCLES. The cases were exhibited in the new out-patient department of the West London Hospital and discussed in the post-graduate department.

THE first meeting of the Hunterian Society of London was held on October 16th at Simpson's Restaurant, Chancery Lane, E.C. After dinner the President, Dr. FORTESCUE FOX, gave an address on "The breakdowns of middle life"—a summary of many years' work. Dr. ERNEST YOUNG read a paper on "The treatment of dyspepsia in nervous patients." During the evening the following took part in the discussion: the PRESIDENT, Sir BRUCE PORTER, Dr. SANGUINETTI, Dr. YOUNG, Dr. ROSS, Dr. BURNFORD, Dr. ASH, Dr. LANGDON BROWN, and Mr. MORTIMER WOOLF. The next meeting of the Society will be held at the Cutlers' Hall, Warwick Lane, E.C., on November 20th, when Dr. PORTER PHILLIPS will open a discussion on "The position of insanity in criminal law."

ACCORDING to the sixty-sixth report of the West Kent Medico-Chirurgical Society, the 1921-22 session was very successful. The average attendance at meetings was twenty-four, and at the Purvis Oration, which was delivered in December, 1921, by Sir James Purves-Stewart, on "Respiratory disorders of nervous origin," forty members were present. It was decided that medical women, irrespective of their place of residence, should be eligible for membership. The financial position of the Society remains strong, the balance for the year being over £265. Meetings are held in the board room of the Miller Hospital, Greenwich. The president for the ensuing year is Dr. W. H. PAYNE, and the secretary is Dr. C. J. B. BUCHAN, 326, Brownhill Road, Catford, S.E.6.

THE third general meeting of the Cambridge University Medical Society was held on November 1st, when Dr. BERNARD SPILSBURY, lecturer on morbid anatomy at St. Bartholomew's Hospital, gave an interesting and instructive lecture entitled "The criminal court and the medical witness." In concluding his lecture Dr. Spilsbury expressed the hope that he had said enough to arouse in the minds of medical students at Cambridge a good deal of enthusiasm for the subject of medical jurisprudence.

Rebicus:

CLINICAL AND OPERATIVE GYNAECOLOGY.

Those who are familiar with Professor MUNRO KERR's valuable book on *Operative Midwifery*—and their name must be legion—will have noted with interest and high expectation the announcement that a volume by him on *Clinical and Operative Gynaecology* had been added to the list of the Oxford Medical Publications. At the outset it should be stated that the two books are not quite on the same plane. The earlier was a treatise on operative obstetrics written by an obstetrician of large experience, and it is so much thought of and so frequently quoted by his fellow specialists as to have acquired the rank of the standard British authority on the subject. The new volume is avowedly no treatise, but, according to the publishers' circular, is designed as a book to which the general practitioner can turn when faced with a gynaecological case which presents difficulties to him, or when he desires to refresh his knowledge. The clinical aspects of the subject are therefore kept uniformly to the front, and only so much anatomy, physiology, and pathology is offered as is considered essential to the proper comprehension of the clinical conditions. At the same time the book is no mere index of gynaecological treatment; rather might it be described as a presentation of the clinical knowledge of a practical teacher of ripe experience. The various points are illustrated throughout by short extracts from the author's notes of actual cases, a method which appeals to readers, and which in the present volume has been used with commendable brevity and not pushed to the point of wearisomeness.

Like "all Gaul," the volume has been divided into three parts. The first and largest is devoted to clinical gynaecology proper. Opening with a chapter of useful generalizations on the etiology, symptomatology, and principles of treatment, the author passes on to the usual summary of female pelvic anatomy. Next the examination of the patient is the subject of a full description; here five pages are occupied by a series of very small diagrams illustrating the various likely and unlikely swellings and resistances that may be found on pelvic examination. We must admire the artistic ingenuity displayed, but it is open to question whether the help the reader will derive from the diagrams justifies the space they occupy. The two succeeding chapters deal with the physiological functions of ovulation and menstruation and their disorders, and the author does not hesitate to dogmatize on points such as the cause and real significance of menstruation, which are still subjects of inquiry and speculation. The author's attitude to some of the more recent work on menstruation, as summarized, for example, in Novak's monograph, is not made evident. This chapter is followed by one on nervous disorders in relation to abdominal and pelvic disease written with characteristic ability and erudition by Dr. Ivy McKenzie, who shows himself a master of the subject and eminently qualified to expound the present state of knowledge of this highly complex relationship. Professor Bryce contributes an account of the development of the reproductive organs as a preface to the discussion of malformation.

Professor Munro Kerr then takes up the thread again in two excellent and practical chapters on displacements and injuries. With a view to simplifying the subject to the practitioner, he has deliberately departed from a strictly pathological classification of the various clinical conditions. While this may be regretted from the educational point of view and also from that of scientific accuracy, we cannot but agree that a strict adherence to any such schemes as have already been devised presents difficulties, especially in a book of this kind. Amends for his heresy are, however, amply provided in a chapter on general considerations regarding infective disease of the reproductive system. It is interesting to have a British authority declare in no uncertain terms his opinion that puerperal infection is a more common cause of pyosalpinx than gonorrhoea. We believe that other gynaecologists in Great Britain are of the same opinion (see, for instance, the recent *Encyclopaedia of Midwifery and Diseases of Women*, edited by Dr. Fairbairn), but the almost unanimous voice of American and Continental writers would lead one to consider

the gonococcus blameworthy in the vast majority of such cases. Professor Munro Kerr points out also that even where the gonococcus is the primary infective agent the main damage to the tubes is the work of the almost inevitable secondary infection by the *Bacillus coli*. Venereal diseases are discussed in detail in an interesting special chapter by Dr. David Watson. With regard to the vexed question of chronic endometritis the view expressed is that, in addition to the true inflammatory "interstitial" form, a "glandular endometritis" of infective origin is also sometimes found. This we believe to be more consistent with general experience than the extreme position taken up by some recent writers.

A practical and adequately full discussion of uterine tumours is followed by chapters describing the infections and new growths of the tubes. The chapter on ectopic pregnancy is one of the best and most practical in the book, and deals very fully and lucidly with the great difficulties that may be encountered in making the all-important diagnosis of this condition. Affections of the peritoneum and cellular tissue and diseases and new growths of the ovary occupy the next two chapters; finally there is a brief discussion of such renal, uterine, vesical, and bowel diseases as may complicate or simulate conditions more strictly gynaecological.

The second part consists of a single chapter on the medical treatment of gynaecological affections, including electrical and radiological methods. In the treatment of menorrhagia due to subinvolution in women near the menopause, Professor Munro Kerr recommends the Roentgen rays—after a curettage to exclude malignant disease or endometrium. He reserves his of fibroids by the rays; on the subject of radium in cancer also he preserves an open mind tinged with hopefulness for the future developments of the method. Up to date he has not had any actual cure, but he has found a preliminary irradiation facilitate the performance of the radical operation. Dr. Hendry contributes to this section an interesting page or two on the importance of proper diet and the regulation of metabolism in gynaecological cases.

The third part deals with operative gynaecology, and opens with general introductory sections on the preparations for operation, post-operative treatment and complications, and general technique. Special sections are contributed on anaesthesia by Dr. Paton Boyd, and on blood transfusion by Dr. W. Rankin. Thereafter the various minor and major operations are described seriatim. The method adopted is admirable in conception and intention, and only a little less excellent in performance. In the case of each operation two or three drawings of the essential steps are given on the right-hand page, while on the left-hand page is the descriptive letterpress, paragraphed to correspond with the figures. It is thus easy even for a beginner to follow the steps as illustrated, and our only criticism is that in some cases the illustrations are not sufficiently numerous, gaps being left which may not easily be bridged by readers who are unfamiliar with the technique. On the whole, however, both Mr. A. K. Maxwell's drawings and the letterpress are adequate.

In this last section it would seem as though the author had altered somewhat his conception of the aim of his book, for he describes and illustrates several operative methods to which only specialists are likely to resort—for example, the various methods of decollation and bisection of the uterus in difficult cases of pyosalpinx. Baldwin's operation for the formation of an artificial vagina from a loop of ileum seems even more conspicuously out of place, as its justifiability in any circumstances is challenged by some eminent gynaecologists.

Professor Munro Kerr's position and his long experience as a practising gynaecologist are sufficient warrant for the soundness of the doctrine contained in this book. His experience as a lecturer and his reputation as an author provide a similar guarantee of the lucidity of his teaching. It is perhaps the very easiness of his style that gives rise to just a suspicion of desultoriness in parts. The author has confessedly avoided writing a "treatise," and what we mean may perhaps be better conveyed by saying that, compared with the almost photographic precision of outline to which most modern textbooks of a comparable size have, as we think very properly, accustomed us, he has adopted an impressionistic style. Obviously, however, it is an arguable point whether this is to be deprecated; and, whether it be or not, the book remains a notable addition to British gynaecological literature.

SURGICAL DISEASES OF CHILDREN.

In his preface Mr. Pybus says that his book, *The Surgical Diseases of Children*,² does not pretend to be a complete treatise, but rather a record of personal experience of the commoner conditions met with on the surgical side of a children's hospital. It is probably for this reason that it is so readable, and that even for those of experience it is interesting and instructive. To the house-surgeon it should be invaluable, for some of its best paragraphs are those on signs and symptoms, their valuation and use in differential diagnosis. Despite brevity, and without sacrifice of definite statement, the author yet manages to convey his sense of the element of uncertainty that occasionally besets the accurate recognition of cases usually simple; the reader will have the more confidence in the positive assertions. The book is divided into twelve sections, which deal in turn with congenital malformations; injuries, including birth injuries, fractures, and dislocations; deformities; cysts and tumours; acute infectious; tuberculosis; congenital syphilis; abdominal infections; diseases of the rectum; diseases of the head; and surgery of the ear. As, added to these, on examination and general treatment, it will be seen that the whole ground is pretty well covered. It is notable that of 162 children admitted, 32 per cent. had acetonaemia on entry, 25 per cent. had it before operation, and no less than 83 per cent. showed it afterwards. Carbohydrates are administered right up to the time of operation—a meal of porridge and treacle four hours before—and glucose is given by mouth and rectum as soon as possible afterwards.

In relation to congenital malformations generally, it seems that the author is something of an optimist, and that certainly implies the only spirit in which their treatment can be brought to a satisfactory result. The account of spina bifida is clear and well judged. The Spitzky splints for fractures in infants are well figured; they should be better known. Only about forty pages are devoted to deformities, so that the descriptions are a little sketchy, and rickets as a disease of metabolism might well have had more space. Scurvy-rickets has only passing mention. In the chapter on cysts, hygroma appears as a simple affair, and the student gets no hint of the disasters that sometimes attend its course. The pyogenic affections, whether of the soft parts, the bones, or of the joints, are admirably reviewed, and the account of the tuberculous invasions of bones and joints which follows, maintains the continuity of pathology and of underlying principle in treatment, as logically it should.

Most of what is written about abdominal diseases is to the point, but some paragraphs are by no means easy to understand. The "treatment" of appendicitis on page 317 has been badly paragraphed or hastily written. Does the author really mean that he would postpone operation when peritonitis is spreading, and leave the initial focus? If so he has returned to the German and French practice of twenty years ago—and perhaps he is right.

The section on genito-urinary troubles is quite adequate, and that on the tonsils, adenoids, and the mastoid sound. Formal circumcision is said to be "rarely necessary" and an incision of the prepuce along the dorsum all that is wanted. Does this not often leave a pendulous and useless piece of tissue?

The volume as a whole is so satisfactory, so compact, so pertinently illustrated, that a second edition is sure to be needed very soon. So good a book deserves a more careful proof reader; it is doubtless pedantic "to never split" an infinitive, but the verb should agree with its subject, and relatives deserve respect. However, students are not grammatical purists, and there is ample reason to recommend the book to them heartily.

PENAL DISCIPLINE.

AFTER thirteen years of official life as H.M. Inspector of Female Prisons, Dr. Mary Gordon has given earnest expression to the conclusions she has reached on our present penal methods and their results in a book recently issued under the title of *Penal Discipline*.³ The book

will undoubtedly be widely read and discussed, and the more widely the better. Vigorous, racy, at times poetical in language, and throughout imbued with an active living sympathy for the derelict and diseased, it is the work of one who sees her fellow man or fellow woman even in the most abandoned criminal or "old lag."

We propose to give an account of Dr. Gordon's line of argument, and to reserve any words of criticism for the end. She tells us that in her conversations with prisoners in their cells they spoke about "topics that made life real to each of us—of men, or children, or drink; of money, or bets, or debts; of revenge, or of unlawful acquisition of lovers, or clothes, or of the sport of evading citizens' duties, or the police." So, to quote her own words, she "haunted the souls of others round their prison cells, and out at the doors, and under the proud waters that had gone over them, or over the mountain tops that had baulked them, and so back to their prison again." Those who have breathed prison official atmosphere for any length of time will not be surprised, therefore, at her statement that at her first round of inspections she unwittingly provided a sensation in several prisons, and also that, as an official, she fears she was never true to type. An imperfect official Dr. Gordon evidently was and must ever remain. It is to be doubted, however, whether outside the world of subordinate officers the perfect official exists; the higher and better the official, the less likely are humanity and sound common sense to be strangled in the coils of red tape. The book, however, is not a criticism of officialdom. Dr. Gordon sets out with the proposition that the prison system, with its principle of penal discipline, has not been made by the administrative body, but by the people of this country, citizens and voters. If, therefore, as Dr. Gordon avers, she found nothing in the prison system to interest her except as a gigantic irrelevance, a social curiosity; if she failed to mark a good effect on any prisoner, but, on the other hand, had no shadow of doubt either of the power of the system to demoralize or of its cruelty; if, as she says, we not only do not deter but actually make over the criminal to crime; and if, as is implied throughout, the whole system is futile and unscientific, the author lays the blame at the door of the public and not at that of its servants.

Dr. Gordon holds that the belief that punishment—that is to say, punishment by imprisonment—defers from crime is an assumption in large measure unfounded. She admits that "bodies of persons may be, and indeed are, deterred by the punishments they have ordained as the result of their findings," and that "those to whom imprisonment does represent a disgraceful and real punishment, on the whole take care not to incur it"—that is, if we take her rightly, the threat of imprisonment deters only the lawfully minded citizens who in the main do not require it, and affects hardly at all those who have actually experienced it. As one of the chief justifications for inflicting punishment is its deterrent influence, this is a serious statement. The great and steady diminution in the prison population of recent years is to be explained otherwise, Dr. Gordon suggests. She points out that, taking at random the years 1909 to 1914, while the number of men sent to prison during that period fell by 41,696, certain degraded offences—for example, rape, defilement of girls, procuring abortion, etc.—increased both relatively and absolutely. Her argument, we take it, is that the nature of the offences for which imprisonment has been awarded, rather than the total number of offenders sent to prison, truly reflects the actual position. The local prison for the petty offender, according to her experience, soon becomes a model lodging-house, a place of recuperation for another "bust," and a manufactory of "recidivists"; if it be a fact that imprisonment and the threat of it do not deter from crime, then the system must be an "expensive absurdity."

Dr. Gordon is on surer ground when she describes the effect of imprisonment on the imprisoned. In a chapter on "Systems and their fruits" she deals with results, and makes the striking statement that, whilst of 14,557 women in local prisons only 1 in 766 was punished for violence, and in convict prisons 1 in 26, no fewer than 1 in every 2 girls in Borstal and Aylesbury was so punished and 1 in every 8 had to be put in irons. This was in 1921, which Dr. Gordon says was an exceptional year. Of the Borstal boys, who were five times as many in number, only 1 in 226 was put in irons—a contrast which we cannot pretend to explain. Dr. Gordon does not question that the conduct of the girls was bad, but in the next chapter, on "Psychical considerations," she propounds a reason for their badness.

² *The Surgical Diseases of Children: A Handbook for Students and Practitioners.* By F. C. Pybus, M.S., F.R.C.S. London: H. K. Lewis and Co. 1922. (D. my 8vo. pp. xviii+408; 228 illustrations. 18s. net.)

³ *Penal Discipline.* By Mary Gordon, L.R.C.P., L.R.C.S.E. tin., L.R.F.P., and S.Glass., late H.M. Inspector of Prisons and Assistant Inspector of State and Certified Inebriate Reformatories. London: George Routledge and Sons, Ltd.; New York: E. P. Dutton and Co. 1922. (Demy. pp. 238; illustrated. 7s. 6d. net.)

Modern psychology is largely based on a study of the primitive instincts and emotions, whereas a prison, Dr. Gordon says, has no use for the emotions. "The prisoner's part is to do as she is told and consume her own smoke." In the words which we have put in italics Dr. Gordon sees the effective reason for much of the badness she finds in the Borstal prisoner. Repression of normal instincts and of acquired tastes and cravings; emotional conflicts; fantasy formation, fostered by long solitudes as the only escape from a cast-iron machine, and the development of an underground mental life detached from a reality in which she has lost all interest, in the author's view, play their part in the moral and intellectual deterioration of the long-term prisoner. The result of her observations has convinced her that of those known in prisons as "feeble-minded" the vast majority are cases of hysteroid or paranoid psychoses. While she admits that all such do not originate in prison, she seems to consider that, in most cases, our penal system is responsible.

It is probably true that, in all but a few, long imprisonment maims as surely as the forfeiture of a limb, by undermining the prisoner's self-respect, initiative, and resource; thus he may become unfitted for the struggle for existence which awaits him outside the prison walls. The lectures, debates, and concerts which are now part of the prison system, the weekly summary of news read by the governor or chaplain, to which innovations reference is made in the Prison Commissioners' Report just issued, are all to the good. They furnish food for the mind but do little to improve the character. If, as has been suggested, an understanding with trade unions can be reached which would enable prison authorities to obtain partial access to the outside market, or if such a system of employing prisoners on a remunerative basis, as Dr. Gordon found in French prisons, were introduced, much of the repression of normal activities, the emotional conflict, and the final apathy and mental deterioration which may attend prolonged imprisonment would perhaps disappear.

Dr. Gordon finds nothing good in the whole of our existing prison system. "Penal discipline," she says, "must go." Instead she would institute "sufficient control to prevent offences, combined with scientific treatment of the prisoner's symptoms, that is, of his crime." Although it is never so stated in terms, it is not unfair to deduce from this that the author generally regards the criminal as a sick person and not as a wrong-doer. Pushed to its logical conclusion the argument of her book is really for a changed public attitude to the criminal, who is to be treated scientifically but neither punished nor reproached. Yet, strangely enough, Dr. Gordon notes the salutary effects of smart punishment on the petty offender. Punishment, even imprisonment, does, in fact, deter. "Control," to be effective, must have power behind. If ever deeply one may disagree with the author's sweeping condemnation of penal discipline, her book opens up many avenues for speculation and is bound to stimulate and beneficially influence reformatory work.

A GERMAN HISTORY OF MEDICINE.

THERE is an idle notion that scholars are dry, dull creatures whose studios have little relation to the real world. The estimate is born of misunderstanding and nursed by ignorance. We conceive that no one to whom has come the privilege of contact with a great scholar can doubt that the qualities which make for success in scholarship would raise a man to eminence in most walks of life. Only direct personal intercourse with such men can reveal the self-discipline, the energy and initiative, the power of organization, the alertness and devotion that go to make up a great work of scholarship. The German history of medicine here reviewed is the joint product of the work of two men who have exhibited these qualities in full measure. Professor Pagel, the founder of the work, died somewhat prematurely in 1912. Professor Sudhoff is happily still with us, and is approaching the 70th year of his life.

Julius Leopold Pagel (1851-1912) was the son of a poor Jewish teacher in Eastern Pomerania. He went early to Berlin for his medical education. Without money or friends he soon made his mark, and while earning his living as a busy and successful general practitioner he yet found time to make considerable additions to the science of medicine. A man of extraordinary intellectual energy and tireless industry he

¹ *Kurzes Handbuch der Geschichte der Medizin*. Von Karl Sudhoff, o.o. Professor der Medizingeschichte an der Universität Götting. Dritte und vierte Auflage von J. L. Pagel's Einführung in die Geschichte der Medizin (1898). Berlin: S. Karger. 1922. (The price should be ascertained from a firm importing German books.)

read very widely and exhibited from the first a strong taste for historical study. His broad, tolerant, and natured outlook and happy literary style especially fitted him for such work, while his great facility as a linguist gave him access to an unusual number of languages both occidental and oriental. He combined with all these qualities exceptional powers as a teacher. The work of such a man was bound to be readable, balanced, and erudite. In spite of his remarkable combination of qualities it was not till 1893, when 47 years old, that Pagel earned any academic recognition, and he did not get the title of professor—and even then it was little but a title—till 1902. No disappointments or failures deterred him, and he continued to turn out a mass of first-class historical work during the remainder of his life.

The keynote of Pagel's writings is their wisdom. He is among the sanest and most far-sighted of historians, his learning never conceals his vision, his opinions are never violent or fanatical, his treatment of a subject is always well proportioned. His book remains perhaps the best single volume history of medicine. Its weak points were certain inaccuracies in detail and indifferent bibliographical records.

The choice of Professor Sudhoff to edit Pagel's book was fortunate. All who follow the output of work on medical history know him for one of the leading living medical historians. His activity is immense and his erudition is combined with the high standard of accuracy demanded by scholarship. His published writings fill a whole shelf and each one of them exhibits originality. This is the second edition of Pagel's work that has passed through Professor Sudhoff's hands. Pagel's errors have been removed, an excellent and well-arranged bibliography has been prepared, and much of the work has been rewritten without changing the original form. Professor Sudhoff has been helped by that promising young Swiss historian, Dr. Henry Sigerist of Zurich, whom we are glad to remember as a student in this country and a guest at the recent International Congress of the History of Medicine in London.

Some may criticize the volume for the comparative compression of the most modern period—a characteristic of all histories of medicine except that of Garrison. The fact is that the qualities needed for the writing of the medical history of the last fifty years are very different from those demanded of the historian of the earlier period. The ideal history of medicine will perhaps be written by two men, one who will treat the subject down to the time of Pasteur and Lister, and the other the period beyond.

Professor Sudhoff is a German of the Germans and as hard a hitter in controversy as a man may be. There could be no doubt on which side a war between England and Germany would find such a man. But clean hard fighting has never been a quality which has earned the dislike of Englishmen, and if he could pay a visit to England he would find fewer onomies than he expected—or hoped for! In the meantime this book, which is generous to a fault in its treatment of English work, confirms his reputation with all scholars. Whatever personal differences may separate men of learning one from another, learning itself ought to be completely international.

THE ELECTRICAL ACTION OF THE HUMAN HEART.

THE late Dr. AUGUSTUS WALLER had intended to publish in 1914 the lectures he gave in 1913 in the Physiological Laboratory of the University of London. They have now—by the care of his widow, whose death so soon followed his—been brought out, with a preface written this year, under the title *The Electrical Action of the Human Heart*.¹

Of the four lectures, the first gives an account of his demonstration in 1889, before the International Congress of Physiology at Bale, of the data, arguments, and conclusions concerning the electrical changes in the human heart as shown by Lippmann's electrometer. The second lecture, describing a demonstration given in 1894, followed Einthoven's invention of the string galvanometer and his introduction of the alphabetical rubric P.Q.R.S.T. for the waves and wavelets of the normal electro-cardiogram. Of this improvement Dr. Waller remarked that the galvanometer is to the capillary electrometer as a high is to a low power of the microscope, that it opened a new chapter in the clinical study of heart disease, and has played a part in medical literature that shows no sign of

¹ *The Electrical Action of the Human Heart*. By Augustus D. Waller, A. M. Waller, London: University of London, pp. ix + 103; 4 plates, 25 figures. 7s. 6d. net.)

its of the meter between 1903 and 1913. As the two ventricular peaks are the prominent features of the normal electro-cardiogram, and are preceded by a smaller wave due to auricular contraction, the simpler rubric a, V_1, V_{II} is regarded as more convenient than Einthoven's familiar P.Q.R.S.T., which has no particular meaning, but has been faithfully followed by most clinical writers. The last lecture goes over the same ground in terms, and is followed by a summary of physiology, anatomy, heart sounds, and apparatus, the latest entry being under the date 1912.

Presented mainly in the order of their chronological development, the contents of this volume form a useful footnote to the history of physiological researches which when first undertaken had, like many others that subsequently became the basis of medical work, no obvious bearing on practice. They also provide the last record of an enthusiastic and famous physiologist's labours.

SURGERY OF THE HEAD AND NECK FOR DENTISTS.

To supplement for the (German) dentist the surgical knowledge acquired during his prescribed six months' course of general surgery and to bring within the compass of a single volume the surgical conditions he is likely to meet with Dr. SEIFERT, private tutor in the university of Würzburg, has compiled a *Surgery of the head and neck for dentists*.⁶ At present the dentist's choice is between a general system of surgery and a compendium—the one too full of information and the other (anathema to the author) wanting in fundamental information.

In this volume practically every surgical condition of the head and neck is dealt with and the main points of pathology, diagnosis, and treatment are briefly but clearly outlined. The dentist whose knowledge of the surgery of the head and neck went no farther than the covers of this book would still find himself well equipped for his profession. The author reflects the generally received surgical views of pathology, but, we think, insists too much on syphilis and too little on sepsis as causes of chronic glossitis and subsequent cancer. Reading the book, one gets the impression that in Germany the dentist is expected to deal with a far greater range of disease of the neighbouring parts than in England. The treatment of tongue injury, for example, seems often to fall to his lot. At most the English dentist is brought in as a second adviser to extract a tooth.

The illustrations are many and good, that of congenital torticollis being specially noteworthy. The fact that they are taken from actual cases in the author's practice may account for the unfortunate circumstance that malignant diseases are only illustrated in their inoperable stages.

We can recommend the book to those who are able to read German.

MENTAL NURSING.

DR. RICHARD EAGER has written a small book, *Hints to Probationer Nurses in Mental Hospitals*,⁷ which is intended to supply in a small compass the information necessary for the nurse to possess at the outset of his or her training. In the first part the author lays down a number of rules to be observed, gives directions for dealing with the various emergencies which are apt to arise, and outlines the ward duties of the nurse. The second part is theoretical, and consists of an introduction to psychology. Though the author writes clearly on a difficult subject, it is rather doubtful whether this section is wisely included in a book designed for the use of a nurse in the first few months of training. We should have thought there was quite sufficient to engage her attention without being instructed in the meaning of "complexes," the "ceusor," the psychology of dreams, symbolism, and so on. It would have been more profitable, we feel, to have devoted these pages, not to rather unnecessary theory, but to a consideration of those nursing principles which should animate the staff of a mental hospital and are specially necessary in dealing with the insane. The precise

and clear directions which the author provides in the first part will, however, be found definitely helpful to the nurse, and the book should be of value to those for whom it is intended.

NOTES ON BOOKS.

THE eighth volume of the now well-known *Archives of Neurology and Psychiatry*,⁸ issued from the pathological laboratory of the London County Mental Hospitals, consists of a series of papers, nearly all of which have appeared elsewhere. It is, however, very convenient to have so valuable a collection brought together in one volume. Of Sir Frederick Mott's nine contributions to the volume perhaps the most important are those on the pathology of dementia precox. His views on this subject are now well known and have been fully stated by him in our columns; they have commanded the respectful attention of all who take interest in this very common mental disorder. That his opinions appeal more to the pathologist and to the student of endocrinology than to the psychologist may perhaps account for some of the criticism they have provoked. The many beautiful plates which illustrate these papers do much to enhance their interest and value. We are glad to see that Dr. Golli's Croonian lectures on the objective study of neurosis are included in this volume, for they will come as a welcome relief to many who have grown somewhat tired of being compelled to look at this problem from the purely psychological angle only. Now that the bequest of the late Dr. Henry Maudsley has been utilized in the establishment of the hospital bearing his name and doing the work he wished to see done, we may look forward to further contributions towards the elucidation of the many problems, both mental and physical, which still await solution by the scientific investigation of mental disease. In the creation of a wider interest and in the dissemination of new discoveries we have no doubt that these *Archives* will play a worthy part.

Sir R. H. FRITH, whose name is well known as the joint author of an important textbook of hygiene, has occupied some of his leisure since retiring from the Army Medical Service in writing a Christmas gift book, *Birds and Blossoms*,⁹ which possesses the merits of being original and inexpensive. For each month of the year he has composed a little essay on the sights and sounds of that month, and each is illustrated by clever pen-and-ink sketches, mostly of birds. There are also four coloured plates of the flowers of the seasons. The author has an observant eye and a ready pen; he is an optimist and has a good word even for November. His book will appeal to Nature lovers, and will open the eyes of the boy or girl who receives it to what is going on in country lanes and city parks, so making more Nature lovers, to their lifelong happiness.

The new volume¹⁰ of the Edinburgh Veterinary Series from the pen of the Principal of the Royal (Dick) Veterinary College deals with the thorax and abdomen of the horse. It is an account which impresses the reader by its accurate and scholarly descriptions. The description of the thorax will be found to be particularly good, that of the heart and the great vessels being excellent. The abdominal contents are well done, and both parts are adorned by Mr. J. T. Murray's illustrations. Those familiar with his work in Cunningham's *Textbooks of Anatomy* will readily recognize an old friend, and will see that he has now done for the horse what he first did for man.

The *Life and Times of Ambroise Paré*, which Dr. PACKARD published through Paul B. Hoeber of New York a year ago, is now published in this country by the Oxford University Press (London: Humphrey Milford. 1922. Price 28s. net). The only difference between the two issues is that the Oxford University Press has prepared a new title-page. The book appears to be printed from the American plates. It was reviewed in our issue of December 3rd, 1921 (p. 949). In the same way Sir JOHN HARINGTON's English version of the *Regimen of the School of Salernum*, published by P. Hoeber in New York in 1920 and reviewed in our columns on February 12th, 1921 (p. 231), has been taken over by the Oxford University Press (price 14s.). We mentioned recently that Hoeber's edition of the *Gold-Headed Cane* will in future be published in this country by the Oxford Press (price 16s.).

⁶ *Chirurgie des Kopfes und Halses für Zahnärzte*. By Dr. Ernst Seifert. München: J. F. Lehmann. 1922. (Roy. 8vo, pp. 202; 147 figures. 7s. 6d.)

⁷ *Hints to Probationer Nurses in Mental Hospitals*. By Richard Eager, O.B.E., M.D. (Aberd.). London: H. K. Lewis and Co. 1922. (Demy 16mo, pp. 82. 1s. 6d. net.)

⁸ *Archives of Neurology and Psychiatry*. Vol. 8. Part 1. London: H. K. Lewis and Co. 1922.

Nobis et Veteris.

SPOLIA NEMORALIA.

(SHRUNK HEADS, EAR-PLUGS, AND LABRETS.)*

BY

SIR JOHN BLAND-SUTTON, F.R.C.S.,
CONSULTING SURGEON TO THE MIDDLESEX HOSPITAL.

INDIANS living in the dense forests bordering the section of the Amazon called the Marañon have acquired notoriety in preparing what are known in England as "shrunk human heads." While on a visit to the Amazon I got some of these curious heads and have been able to examine them critically, and also obtained some stories concerning the Indians.

Recently G. M. Dyott made an adventurous journey across Peru to Iquitos. After being treacherously abandoned by his guide on the return journey, he was rescued by some Aguarunas. Dyott, virtually a prisoner for many weeks, won the confidence of the Indians, and they helped him to reach Lima. While with the Indians he acquired some knowledge of their language, the secrets of the community, and a first-hand knowledge of their customs. These he described in his book entitled *The Silent Highways of the Jungle* (1922).

THE AGUARUNAS: SHRUNK HEADS.

These Indians are well formed, with copper skins and long raven-black hair, which is cut into a fringe across the forehead. The men average in height 5½ ft., the women rarely exceed 5 ft.

The men are clever hunters, use the blow-gun skilfully, and can hit a monkey, as it jumps from tree to tree, with the poisoned dart. They live on bananas, mandioc, and fruit. They also eat fishes, tortoises, sloths, monkeys, small wild pigs, and birds, especially toucans and parrots. The women are drudges; they collect, prepare, and cook the food. The men hunt and fight; in their hours of ease they amuse themselves spinning thread from wild cotton, and weave the material for the scanty clothes they wear.

In civilized countries human beings wear clothes for decency, protection against weather, and for warmth. With the Aguarunas decency does not count. Their scanty clothes protect them against insects and thorns. When it rains they take off their clothes, carefully fold them, and use large palm leaves to keep themselves dry.

The Indian (Fig. 1) shows well the luxuriant growth of hair and its arrangement. This boy is equipped for accompanying his father in the forest. The quiver, made of bamboo, contains light wooden poisoned darts, slender as knitting needles; the gourd attached to it contains a supply of wild cotton, which is used for adjusting the darts to the lumen of the blow-gun.

The pointed tip of a dart is smeared with woorali, the South American arrow poison. A mere scratch of the skin made with the tip of such a dart is quickly fatal, but a moderate quantity of woorali may be swallowed without harm. The flesh of a bird or an animal killed by a poisoned dart is eaten without danger.

The Amazonian Indians are familiar with the process of mummifying dead bodies. As a rule a corpse is flung into the river, but when killed in combat the body is mummified, wrapped in bark, and placed on a stand in the centre of the hut as an object of veneration. Some notion of their methods of mummification may be gathered from the way these Indians treat the heads of victims slain in combat. The conqueror cuts off the head, splits the scalp by a vertical incision in the occipital region (Fig. 2), and neatly removes the skull with the brain, eyes, muscles, jaw, and tongue,

leaving the skin of the face and the scalp intact. The incision is closed with a continuous stitch and the cutaneous bag is packed with hot pebbles, or hot sand, and carefully dried in the sun. When this crude taxidermic process is complete the skin shrinks to the size of an orange, preserving the features. The lips are stitched together with threads, which are left long, and dyed red in such a way as to present alternate bands, coloured and uncoloured (Fig. 3). The lips are sewn together to prevent the victim retorting when his conqueror freely curses him, and to condemn him to eternal silence. A cord is attached to the vertex of the scalp to enable the trophy to be slung on the girdle of the warrior. Some of the cords are decorated with scarlet feathers. The skin of the face is smoked, polished, and sometimes smeared with red dye.

There are two shrunk heads in the Natural History Museum, South Kensington, probably the first examples seen in London. They were shown to the Anthropological Society, Paris, in 1862, by Dr. Moreno-Maiz, formerly surgeon-in-chief of the Peruvian army. He presented them to the museum. The heads were given to Moreno-Maiz by M. Galvey, the Peruvian Minister in Paris; they were found in an Inca tomb in the territory occupied by Jivaros Indians (Ecuador). Moreno-Maiz appreciated the heads as excellent examples of taxidermic art, detected the manner in which the skull had been removed, and the skill with which the shrinking had been carried out with conservation of the features. Dr. Bellaviscencio examined pieces of the mummified skin histologically; sweat glands and their ducts, hair bulbs and sebaceous glands, and the layers of epidermis were easily recognized.

The heads were those of Jivaros warriors, and were probably preserved from religious motives, for these Indians did not bury the heads of the dead with their bodies in cemeteries, but after conservation placed them around their houses and preserved them with respect, for these cherished remains protected the families from their enemies. For these Indians death was not a natural phenomenon—it was a consequence of witchcraft, the occult and culpable action of enemies, known and unknown. Bellaert published a good account of the Jivaros Indian in 1863.

The knowledge of this peculiar method of preserving heads has come down from the Incas of Peru. The body of a deceased Inca was skilfully mummified and removed to the great Temple of the Sun at Cuzco. The Peruvian sovereign on entering the sanctuary of the dead might behold the effigies of his royal ancestors, ranged in opposite files—the men on the right and the queens on their left. The bodies, clothed in the princely attire which they were accustomed to wear, were placed on chairs of gold, their faces exhibiting the natural dusky hue, their forms and lineaments true to life (Prescott). Garcilasso saw them (1560) and described them as "perfect as life without so much as a hair or an eyebrow wanting."

Mummified Incas were treated with reverence, but to-day Indians living in the seclusion of the dense forests are described as devoid of emotions such as love, pity, admiration, wonder, and joy. They are superstitious, and superstition is born of fear of spirits, good and evil. It is difficult to believe, as some assert, that Indians lack imagination, when they practise the diabolical art of curing the skin of an adversary's head, shrink it to the size of a lemon, preserving the features, even the eyelashes and eyebrows, and sew the lips together, so that when they curse the victim the leathery lips can make no reply. Surely belief in spirits, good and evil, depends on the faculty of speech.

In London there is now a fair number of these curious heads available for study. In addition to the two in the heads available for study. In addition to the two in the Natural History Museum the Royal College of Surgeons possesses six, the British Museum three, as well as a collection of hunting and domestic implements used by the Peruvian Indians. The Wellcome Historical Medical Museum contains

FIG. 1.—Aguaruna boy equipped for accompanying his father in the forest. (From a photograph by G. M. Dyott.)

* An address given at a social meeting of the Royal Society of Medicine

FIG. 2.—Shrunk head of an Aguaruna. The hair has been removed from one side to afford a view of the scalp and to expose the line of the incision, which permits the extraction of the skull (half natural size). The material used to sew the lips together is twisted cotton thread. The scalp is stung by a lifted loop.

FIG. 3.—Shrunk head of an Aguaruna (half natural size). The hair is coarse like that of a mane or tail, raven black, and two feet in length. (Museum, Royal College of Surgeons.)

FIG. 4.—Head of a Botocudo with ear-plug and labret.

FIG. 5.—Head of Gotos Indian with ear-plugs (A. Miles Moss).

thirteen examples, and there are many kept as curios by travellers. When a demand for such heads arose many were forthcoming, but traffic in these gruesome curios is discouraged lest it lead to undesirable methods of obtaining them.

EAR-PLUGS AND LABRETS.

When Columbus discovered Honduras during his fourth voyage (1502) he named part of the seaboard "Costa de la Oreja," in reference to the ears of the natives enlarged with plugs. The Indians inhabiting the forests wear ear-plugs and labrets. Some of the tribes were named by the Portuguese "Botocudos" on account of this habit, *botogue* being the Portuguese name for a plug. The ear-plugs of the Botocudos are sometimes four inches in diameter. There are plugs of this size in the British Museum, and they resemble bungs. The plugs can be slipped in and out of the loops like buttons. Some ear lobes are so distended with huge plugs that they reach to the shoulders and resemble the wings of bats (Fig. 4).

Drs. Spix and Martius, in 1817, under the auspices of the King of Bavaria, made a journey for scientific purposes through the Amazonian forests. Spix was responsible for zoology and Martius for botany. They subsequently wrote an instructive book entitled *Travels in Brazil*. The first native American they saw was a boy of the cannibal race called Botocudos. He was in the house of M. von Langsdorff. The story of the boy is curious. A former Minister of State had applied to the district commander for an Indian skull which he required for Professor Blumenbach. The commandant had no opportunity for obtaining a dead specimen, so he sent two living Botocudos, who had been taken in a sudden attack by his soldiers. Von Langsdorff obtained one of them, to whom he soon became much attached, and "who served him not only as a living cabinet piece, but as a collector of objects of natural history." This boy wore not only ear-plugs but also a large labret.

Ear-plugs are instructive in regard to the view that the method of mummifying heads is of Incaian origin. The heir to the Inca throne received a military education with the sons of the nobles. At the age of 16 they were submitted to a public examination in order to show their prowess in the athletic exercises of warriors.

They were admitted into the order of chivalry by the Inca in the following manner: the novice knelt before him and he pierced the lobe of the ear with a golden bodkin, and this hole was gradually dilated until it became large enough to receive an ear-plug. "This monstrous deformity was regarded as a beauty by the natives" (Prescott).

The ears of shrunk heads sometimes contain a wooden spigot in the lobule (Fig. 6). The Royal College of Surgeons contains two examples, and I think this is peculiar to the Jivaros (Ecuador). There is a shrunk head in the British Museum, with preserved skins of brightly coloured birds

hanging as ornaments from the lobe of each ear. Gorgeous plumes of feathers are worn by the men on festive occasions.

It is clear that there are two kinds of shrunk heads—one from enemies slain in combat and the other heads of chiefs. The former are freely cursed by their captors; the latter, decorated with iridescent wing-cases (elytra) of large beetles, bright-coloured feathers, and skins of gaudy birds, are venerated and worshipped as idols.

The Rev. Arthur Miles Moss (1909) made a journey for entomological purposes into the forests of Peru, and succeeded in recovering some photographs, obtained by Mr. Kroehle, of Indians living along the tributaries of the Amazon. Some of these photographs show Gotos Indians with ear-plugs (Fig. 5). Kroehle lived for some time among the Indians and received an arrow wound which "hastened his death." On the back of a photograph is written the significant word, "Anthropophagus."

Spix and Martius reported that the Botocudos were cannibals.

Opportunities for seeing Indians in Brazil with ear-plugs and labrets are rare. In British East Africa they are common, especially among the Masai and Kikuyu. These deformed ears are objects of great pride to their possessors and the envy of their neighbors. To break the loop is an insult. When men quarrel they snatch at the ear-loops and try to break them. If the loop is

FIG. 6.—Shrunk head of a Jivaro Indian with a spigot of wood in the lobe of the ear.

following way: the torn ends are cut so as to leave sloping surfaces; the freshened edges are then superimposed and held in position with the finger and thumb until bleeding completely ceases. The apposed ends of the loop are bound together with a strip from a leaf, a blade of grass, or a piece of bast, and union

quickly follows. Each tribe has a man who performs these operations. Without the plug the large ear-loops resemble rubber rings, and the men loop them over the helix for protection.

It is clear that Amazonian Indians, as well as the natives of East Africa, like surgeons in civilized countries, are familiar with the elastic properties of human skin.

Shrunk heads, ear-plugs, and labrets appeal to me. My father taught me to stuff birds at the time my mother stuffed me with the creed and ten commandments. Later in life I saw savages ornamented with feathers, skins, teeth, and claws in tropical forests; similar decorations are worn by fashionable human beings who strut in Piccadilly or parade the paddock at Ascot.

REPLACEMENT OF CARS: INCOME TAX ALLOWANCE.

THE replacement of a medical practitioner's car frequently raises questions which are not only somewhat involved, but also affect substantially the amount of income tax to be paid. We propose to deal briefly with the matter in general terms in the hope that a few notes may be of assistance to our readers.

The key to the solution of most of the problems lies in a grasp of the distinction between current expenditure and capital outlay; the former is allowable for income tax purposes, but the latter is not. To take a simple case, suppose a medical man setting up in practice for the first time purchases

a car—obviously the cost represents capital outlay; and if a second car is purchased while the first is retained in commission, that expense is precisely similar in its nature. On the other hand, if the second car is bought to replace the first, then the cost of the second car—assuming it is a similar one—less the amount allowed for the old one, represents the current expense of maintaining equipment the cost of which has already been charged to capital. But the facts are seldom as simple as this, because frequently the second car is a better one in grade, power, or condition than the one which is replaced, so that both maintenance and improvement are effected by the one transaction, and then the cost has to be divided accordingly into allowable and capital portions—or, to put the point another way, there has been a real addition

to the original capital outlay, and that addition must be excluded from the total expense for income tax purposes. Assuming for the sake of simplicity that motor prices have remained constant, the adjustment would work out thus:

In 1918 car "A" was purchased at second hand for	... £250
(Original price of car was £500.)	
In 1921 car "A" was sold for £150, and car "B" was bought for	... £500
Net cost of new car = £500 minus £150	... = £350
Amount of capital—that is, improvement—cost	£500
minus £250	... = £250
Allowance for income tax purposes	... £100

Unfortunately for the calculation, motor car prices have not remained constant. The fact that a car bought as a renewal cost more than the car displaced does not at all necessarily imply that it is in any way superior—it may, in fact, be the opposite—but the local inspector of taxes may ignore this special factor and propose to treat the increase in cost as representing further capital outlay. If that increase were likely to be permanent, there might be a good deal to be said for that argument; but, whatever the merits or demerits of the technical question may be, they are, fortunately, only of academic interest, as the matter has been the subject of an authoritative statement. When official evidence was being tendered to the Royal Commission on Income Tax on behalf of the Board of Inland Revenue on the subject of the allowances made for the replacement of machinery and plant—and it is on that footing that motor cars used for professional purposes are dealt with—it was explicitly stated that when replacement was effected by a similar machine at an increased cost the whole of that cost, less the amount received for the machine displaced, would be allowed; and, further, that where an improved machine was purchased the net cost would be allowed up to the amount of the expenditure that would have been incurred if a similar instead of a more expensive machine had been purchased. An example may make the point clearer:

In 1916 original car "C" bought for	... £300
(In 1921 a similar car would have cost £400.)	
In 1921 a superior car "D" was bought for	... £500
(The car "C" being sold for £150.)	
The net cost of purchase is £500 minus £150 =	... £350
The capital outlay is £500 minus £400	... £100
The net cost of "replacement" allowable is	... £250

It is on this kind of case that discussions most frequently arise, some inspectors being apparently inclined to treat the capital outlay as the increase in the amount paid for the car—that is, £500 minus £300 = £200; and there is the further practical difficulty that there is sometimes no car on the market similar to the old car, in which case the sum represented in the above example by the amount of £400 has to be estimated—a question that is a particularly open one when the car replaced had been purchased at second hand, so that its then condition is an important factor in the problem. If, however, the principle is accepted, the figures can usually be agreed with the inspector of taxes by correspondence or by word of mouth.

It may be advisable to add that in the future falling prices will reverse the facts in many cases, and that a practitioner cannot claim a greater deduction than the net cost of replacing a car, even though the price of the new car is less than the original outlay on the car which he is thereby replacing. For instance, supposing that in the second example given above car "C" is replaced by a similar car "E," costing £250, then the amount to be allowed is the actual out-of-pocket expenditure—namely, £250 minus £150 = £100.

THE LONDON SCHOOL OF TROPICAL MEDICINE.

The annual dinner of the London School of Tropical Medicine was held on November 1st, under the chairmanship of Dr. HUGH STANNUS, a former student. Many past and present students and members of the staff were present; among the guests were Sir William Leishman and Sir George Newman and Sir Arthur Robinson of the Ministry of Health.

The CHAIRMAN, in giving the toast of the School, said that this year they had to mourn the loss of the man who conceived the idea of a tropical school in London. The genius of Sir Patrick Manson had been recognized in every country, and the results of his work were reflected over a great area of the globe. Students who came under the spell of the man himself would remember him as the grand old man of tropical medicine, who was above all things himself a student, a seeker after truth, a keen investigator, a man of courage, imagination, and reasoning power. Manson created

in the School of Tropical Medicine a tradition which would be an inspiration to many generations. The number of students who had passed through the School had now reached a very large total. The School had established a stranglehold upon diseases around the equatorial regions of the earth, and the noose was being drawn tighter every year. The life of the student was strenuous—at one moment invited to play an incinerator, at another to demonstrate a splenectomy, now examining with the ophthalmoscope the window through which the soul of man looked out, and now with the sigmoidoscope investigating the depths of the internal economy. Into the vast area of tropical medicine specialization had already entered, with its advantages and disadvantages, but it seemed that the walls of division between tropical and general medicine were fast crumbling. The investigation of ordinary diseases among tropical populations would well repay research in the future. The biochemist, again, had hardly touched as yet the fringe of tropical pathology. The practitioner in the tropics must be something of an anthropologist and a psychologist as well, for the mental outlook, the religious belief, and the social custom had to be reckoned with in studying disease.

Proposed Incorporation with the New Institute of Hygiene.

SIR ARTHUR CLARKE, in proposing the toast of the guests, alluded to the negotiations now proceeding whereby the School may become incorporated with the new School of Hygiene in London, founded with the assistance of the generous gift made by the Rockefeller Fund. This matter had given much anxiety to the Board of Governors of the Seamen's Hospital Society, which had seen the school grow up under its care, and had placed it in its present absolutely sound financial position, while its success in teaching and research had been assured by the genius of Sir Patrick Manson and the ability of the teaching staff. If any such change came about it must be because it was in the best interests of tropical medicine and research and of the School itself as the teaching centre.

SIR ARTHUR ROBINSON, Permanent Secretary of the Ministry of Health, said that the question of incorporation with the School of Hygiene was one to which he could not make any extended reference. The essence of the proposal was that there was room in London for a school of instruction and research in public health, interpreting that term in the widest possible sense, national, imperial, and international. That was the conception put to the Rockefeller Foundation, and to carry it out the Foundation had made its magnificent gift. To this the British Government had replied by undertaking to meet the expense of running the institution when established. Progress had been made to the extent that a site had already been secured. The new institution must in any event have a close relation with the London School of Tropical Medicine, and it should if possible, and if it was agreed on all sides, amalgamate with the School. Speaking quite broadly, he would say that any amalgamation must be such as to secure the continuance of the great work done by the Tropical School. That was the fundamental condition. The Ministry of Health had to consider the subject from that point of view, and it was from that point of view that the Ministry had made certain proposals to the Seamen's Hospital Society. The great work of the School, and the fact that it had traditions, formed and forming, must always be kept in mind, and if amalgamation came about everything must be done to preserve the traditions of the Tropical School and to carry on and expand its work as part of the great general work of public health. The proposal was still under consideration, and the Ministry of Health, the Rockefeller Foundation, and the University of London, with which the School of Tropical Medicine was associated, would welcome the amalgamation most heartily if such a solution were found possible. If the amalgamation came about it would be on fair terms, and such as to secure the continuance of the work and to uphold the traditions of the School.

SIR HAVELOCK CHARLES, Dean of the School, said that evidently there was a marriage in contemplation, the bride being the School, and it was only right and proper to consider the marriage settlements, for otherwise the bride did not know what might happen to her once the ceremony was over. The Tropical School was in a first-rate financial condition. All that it required to complete its equipment were laboratories for tropical hygiene. He thought he was expressing the desire of staff and students when he said that if the School was met fairly and well in its aspirations their loyal support of the new arrangement could be counted upon.

British Medical Journal.

SATURDAY, NOVEMBER 11TH, 1922.

THE STATISTICAL METHOD IN PSYCHOLOGICAL ANALYSIS.

IN his presidential address to the Medical Society of London Lord Dawson stated his belief that fuller and franker discussion of psycho-pathology within the profession was needed. Although Lord Dawson did not confine his remarks to the particular nexus of theory and practice popularly termed "psycho-analysis," he did refer specifically to that branch of the subject and in terms which, but a few years ago, were unusual. The psychological doctrines associated with the name of Freud have been debated in the columns of the medical press for more than ten years, with irregular epidemic exacerbations. Some six or seven years ago many distinguished members of the profession fell victims; a majority of them used language very different from that of Lord Dawson. Something must be credited to the war-time atmosphere, more to the example of an able polemist who expressed convictions, sincerely held, with more vigour than charity. It is at least certain, as the style of a current controversy testifies, that one obstacle to the discussion advocated by Lord Dawson has been overcome.

But although discussion of this topic is now more courteous—at least in professional journals—and accusations that "psycho-analysts" are corruptors of school children to be restrained by hierarchical authority are no longer popular even in the lay press, we are not sure that much progress towards intellectual agreement has been made. Perhaps a metaphor of Lord Dawson's gives us a clue. He spoke of mental surgery. Before we are in a position to canvass different operative methods we ought to have reached a measure of agreement on topographical anatomy. Sir Clifford Allbutt recently said that "popular psycho-analysis was false science; it had no units, no means of measurement, no separation of objective and subjective evidence," and he stigmatized psycho-analytical interpretations of dreams as "incredible nonsense." Sir Clifford was explicitly referring to popular "psycho-analysis," which we apprehend to be that form reprobated by Dean Inge as "a fashionable craze," especially of "flighty young women"—no doubt the people who have analysed so many school children—but it is pertinent to ask what attempts have been or can be made to apply to serious "psycho-analysis" logical criteria commensurable with those held to be applicable to other clinical procedures. Our grandfathers frequently discussed the diagnosis and treatment of "fevers." If—as may perhaps have been the case—some relied upon the use of a clinical thermometer, which others rejected as a new fangled, unreliable, and nonsensical instrument, there could be no agreement until a preliminary inquiry had settled whether the clinical thermometer was or was not a tool that could be trusted. We seem to be—we speak of the general body of the profession, not of the specialists—rather in this position. There is no agreement as to the precision of the diagnostic tools; this, then, is a point which should first be debated.

These reflections are suggested by an article on the question of the interpretation of dreams by Dr. A. v. Muralt of Zürich which appeared in a recent issue of the *Schweizer Archiv für Neurologie und Psychiatrie*.²

The problem Dr. v. Muralt set himself was this: If the record of a dream, the associations of that dream and the clinical history of the patient, as elicited by ordinary interrogation prior to the first analytical sitting, are submitted to a series of independent observers, will their interpretations be sufficiently concordant and sufficiently consistent with the subsequent history of the case to justify us in attaching scientific importance to the method of dream analysis? Including his own (written down immediately after the event), Dr. v. Muralt had seven interpretations of the dream, the collation of which has prompted him to write: "My investigation has, in my opinion, provided a proof—a point to which I desire to give special prominence—that different interpreters of the same dream material arrive at similar conclusions, and that therefore the interpretation of dreams is as a method on an equal footing with other scientific methods."

The field of experiment upon which Dr. v. Muralt has entered seems promising, although we cannot endorse the conclusion quoted. The arithmetical assessment of the value of testimony upon which Poisson expended so much mathematical genius did not, perhaps, deserve the scorn of Bertrand nor the more recently expressed contempt of Mr. J. M. Keynes, but it is undoubtedly a process beset with difficulties. If seven persons independently asserted, and correctly asserted, that a card turned up from a shuffled pack by an operator invisible to them was a heart, it might be rational to say that the odds against "chance" were thousands to one. But if beforehand they had read and believed a statement that it was a law of nature that a card turned up by a concealed operator was usually a heart, the seven would be reduced to a unit and the odds be only three to one. Now this argument weakens the value of evidence to which Dr. v. Muralt attaches importance. An incident of his patient's dream was the preparation of a sermon in the dreamer's father's study (the dreamer was a young student of theology, the son of a pastor). Associations with the dreamed incident were: "I have worked a great deal in this study with my father—Papa—I got on very well with him, we have the same ideas." The patient's symptoms were a scrupulosity and an indecision almost amounting to doubting mania. That all seven interpreters, all familiar with the writings of Freud and Jung, should attach significance to the relation with the father is not, we think, at all remarkable. A similar exegesis might be applied to the less complete but substantial agreement between the interpreters on the significance of other incidents in the dream.

The story presents other points of interest. We begin with a patient whose life is a misery to himself. Among the clinical data of the case we have a dream which, on the face of it, is more nonsense. By the application to this material of certain rules—which, if we please, we may regard as quite arbitrary—certain diagnostic inferences are drawn. The subsequent history of the case is consistent with the truth of the diagnosis. Is the concordance fortuitous? The answer must depend on a knowledge of the frequency with which dream incidents of the type considered occur in the experience of youths not on the verge of mental collapse; the collection and analysis of such data is difficult, but not beyond the bounds of research possible for non-specialist medical men. We are not called upon to enter into the minutiae of the theory; we can begin with the broadest categories of dream types and ascertain their frequency in a normal population. It is hopeless to expect the adepts to do this for us. They, rightly or wrongly, are satisfied that their rules are correct. To apply the numerical method of Louis to this subject is more laborious and less flattering to one's intellectual vanity than abstract disquisition, but it is a scientific method. We recall

the literary history of masturbation, set out in one of Dr. Havelock Ellis's volumes. From the beginning of the eighteenth down to well past the middle of the nineteenth century there was hardly any physical or mental symptom which had not been specifically attributed by some eminent authority to the practice of masturbation. It was not until within living memory that the numerical method was applied to this problem, when it was found that a large proportion (in some samples a very large majority) of apparently healthy adolescents had been or were masturbators. This result certainly did not prove that masturbation was a harmless practice, but it did prove that the etiological significance of the high proportion of masturbators amongst the neurotic or psychotic was dubious. A comparison between the statements on the subject in textbooks of this and of the last generation will bring out the point we are attempting to make.

In our opinion, neither denunciations of the absurdity of the Freudian dream analysis nor pragmatic justifications of its success are adequate substitutes for a statistical verification. The significance of Dr. v. Mural's paper lies not in its positive contribution to knowledge, not even in the precise numerical method adopted by him, but in the thesis that this problem too should be studied by the statistical method. Dream analysis is, of course, only one of the instruments of the analytical psychologists; it is perhaps the most disputable. But it seems to be one which can be tested in the domain of psychological experience accessible to all of us.

THE SMALL-POX OUTBREAK.

In an article at p. 943 of our present issue an account is given in detail of the measures which have been taken at and in connexion with Poplar workhouse to control the small outbreak of small-pox within the institution, and to try to prevent its extension outside. The three great measures are: first, vaccination of inmates and of officers, whether resident or not; secondly, search for contacts, with a view to their vaccination if discovered in time to enable vaccine to overtake variola, and surveillance so that they may immediately be isolated if the initial symptoms of small-pox appear; and, thirdly, hospital isolation forthwith of all discovered cases. Needless to say, disinfection and cleansing fall also within the scheme.

Experience indicates that though small-pox may come at any time, its extension is specially to be feared in winter, and we are now at the onset of that season. Also in the present outbreak a virulence of type is manifesting itself of which this country has seen comparatively little for a long time. Small-pox in most parts of Britain has in recent years been very mild, with a remarkably low fatality rate, such as has been experienced likewise in South Africa, Australia, and North America. Whether that strain of infection is now to be displaced with us by the kind of disease which was familiar half a century ago it is impossible to forecast, but there is undoubted cause for apprehension. A third factor in the case is the unprotected condition of a large section of the population, especially at the younger ages, owing to neglect of vaccination. On the other hand, the work of vaccination and revaccination carried out in the Forces during the war has conferred a large measure of protection upon the male adults of the country.

It is very satisfactory that the Ministry of Health is acting with foresight and promptitude. We have received a copy of two memoranda which are being issued, one to boards of guardians as the statutory authorities for vaccination, and the other to sanitary authorities as responsible generally for the public health. Both documents are distinguished alike by intimate knowledge and

by common sense. In respect of contacts there is no exhibition of panic. They are not to be isolated either at home or in reception houses, as being capable of spreading the disease before it manifests itself on their own persons; but when the time comes at which the disease is likely to appear, in cases where it may have been incubating, surveillance is to be very thorough. Of course, for common lodging houses, with their casual and constantly changing inmates, special measures would have to be resorted to.

Satisfactory features of the position are that all who are now, in presence of the danger, successfully vaccinated will have the benefit of the recency of their vaccination. If an epidemic should come, it will be well past before the protective operation has had time to lose any of its initial value. Another comforting fact is that calf lymph can be quickly produced in quantity sufficient to meet the most extensive epidemic. That is a position very different from the times when the only source of lymph was from newly vaccinated babies, and when the supply was limited by the weekly vaccinations.

THE FIELD LABORATORIES, SHEFFIELD.

We publish elsewhere (p. 941) a remarkable address given by Sir Walter Fletcher, Secretary of the Medical Research Council, on a remarkable occasion. The occasion was remarkable for several reasons. In the first place it recalled the generous gift of the Sheffield Panel Committee of £1,000 towards the cost of erecting the Field Laboratories which are under the direction of Dr. Edward Mellanby, professor of pharmacology in the University of Sheffield. The Sheffield Panel Committee is financed, we understand, by a purely voluntary scheme, and when the financial situation was reviewed at the beginning of 1921 it was seen that economies practised had resulted in a considerable surplus, so that not only could the voluntary levy be suspended, but there remained over a sum of about £1,000. At a meeting of the insurance practitioners it was resolved that this sum should be transferred to the University, with a request that it should be earmarked for the equipment of the Field Research Laboratory. Professor Mellanby's department consists of a laboratory for experimental pharmacology at the University and of the Field Laboratories for dietetic experiments. The importance of associating the pharmacology department with clinical work is fully recognized in Sheffield, and Professor Mellanby has been appointed one of the honorary physicians to the Royal Infirmary, where the other physicians have given up 24 beds to him. In the curriculum at Sheffield students take part of the courses in physiology and anatomy, and the course in pharmacology while also doing elementary ward work; in this way it is hoped to bring the methods of the laboratory into closer touch not only with the clinical practice of physicians and surgeons but with the minds of the students also. The hope seems likely to be fulfilled, for students are displaying keen interest in the opportunities afforded to them. Sir Walter Fletcher's address was remarkable for many reasons: for once in a way he took for his subject the importance of medical research work in the daily life of the community. Workers in research, among whom he himself holds so distinguished a position, are too much fascinated by its interest and beauty often to explain themselves to the public, and he asked for the co-operation of practising members of the profession to act as interpreters of laboratory work to the public as they were already prepared to make use of the results of scientific research for the benefit of the public. Very happily he took for the text of a large part of his address the dictum of a one-time Minister who "did not hold with research, but believed that if disease was to be stopped the people must have better grub and less dirt." The fact that the occasion of the meeting he was addressing was the examination of some of the work Professor Mellanby is doing with regard to

deficiency diseases afforded an illustration to his hand of how "better grub" is to be provided, or at any rate of how its goodness in the promotion of growth in children and the prevention of disease in man can be judged by such researches as those now being carried out at Sheffield. The effects observed, under rigid conditions, of the withdrawal of vitamins are so astonishing that it is almost true to say that they must be seen to be believed, but no one who has seen them can doubt that a deficient supply of vitamins, short of their total withdrawal, must produce depressing effects on nutrition, retarding growth and predisposing to disease. Sir Walter Fletcher touched very lightly on the surprising new work on photo synthesis, which appears to show that direct sunlight, or even artificial light of a suitable kind, falling upon the skin, can stimulate the production of vitamins, or in some way make up for the want of them. We will not attempt to forestall the pleasure members will have in reading Sir Walter Fletcher's address, but we may express our sympathy with his humorous defiance of the people who, when told of a new thing, begin by saying it isn't true, and eventually assert that they know it all the while.

THE LEAGUE OF NATIONS AND THE TRAFFIC IN DANGEROUS DRUGS.

THE third Assembly of the League of Nations, held at Geneva in September, 1922, received a report from its Commission on the Traffic in Opium and Dangerous Drugs. From this it appears that Persia, Albania, Argentina, Colombia, Costa Rica, Esthonia, Luxemburg, and Paraguay have not yet unreservedly ratified the Opium Convention of 1912. Switzerland is expected to ratify by the end of this year, and it is hoped that Persia may shortly withdraw the serious reservations hitherto made. Turkey, of course, is still outside the League and the Convention. Very little progress has been made with the effort supported by the Advisory Committee to secure a system of Government certification from importers of these drugs, to the effect that the consignments are to be used for medical or legitimate purposes only. The success of such a system, it is recognized, is entirely dependent upon its general adoption, and no fewer than twenty-six States, members of the League, have not yet adopted it, although that system was unanimously approved by the second Assembly. A resolution was passed by the third Assembly, on the recommendation of the Commission mentioned above, inviting Governments which are parties to the Opium Convention to refuse licences for import of the drugs to any country which has not ratified the Convention and adopted the system of licence control of exports and imports, subject to the Advisory Committee reporting favourably to the Council on the proposal. The Provisional Health Committee of the League, which was last year requested to report on the amount of morphine, cocaine, heroin, etc., required in different countries for legitimate medical purposes, has not so far concluded any definite results, and a request has been made to all Governments parties to the Convention to furnish estimates of their annual requirements of these drugs as speedily as possible, accompanied by a statement of the method by which the figures are arrived at. It is thus hoped that a provisional estimate of the world's legitimate consumption of the drugs may be arrived at and the way opened for the control of their production. The Commission observes that "as long as the dangerous drugs are produced in quantities exceeding the legitimate requirements, a great danger exists that the surplus will find its way into illegitimate channels. A control of production so as to limit it to the amount required for medical and legitimate purposes will therefore be the most effective way of putting a stop to the illicit traffic." This view has been emphasized in these columns for the last ten years, and we are gratified to find it adopted as a basis of policy by the League of Nations. The Commission recalls that the Opium Convention (Chap. II) contemplates the complete suppression of the traffic in opium prepared for smoking, and draws attention to the somewhat ominous increase of imports of opium into Hong-Kong of from ten to twenty chests a month.

The statistics asked for from the different Governments showing the imports, exports, manufacture, distribution, and consumption of the drugs in question appear to have been very incompletely supplied, and an urgent request is made for fuller statistics for the current year. The Commission justly remarks that "if we are to carry through this great programme we must have the co-operation of all countries which are specially concerned in the cultivation, manufacture, and distribution of the drugs." The report concludes with five resolutions, which were submitted to and passed by the Assembly, embodying the views set out in the report; and the United States, which, like Germany, is not yet a member of the League, was invited to send a representative to the Advisory Committee, as has already been done by the latter Power. Thus all too tardily the provisions of the Opium Convention, already ten years old, are being put into operation. John Stuart Mill in his autobiography notes that "all questions on which there are strong private interests on one side and only the public good on the other have long periods of incubation to go through." The control of drugs of addiction would have served him as a apt illustration of his dictum.

RESEARCH DEFENCE SOCIETY.

It is a grave error to underestimate one's enemies, and it would be well if members of the medical profession reminded themselves more often of this military truism in connexion with the hostile forces of the antivivisectionists. The literature of these "campaigners against cruelty" is so ill informed, their arguments are so full of obvious fallacies, and they betray such naïve narrow-mindedness that medical men and women often dismiss the subject with a smile and shrug of the shoulders, reflecting that cranks are as common as *kranken* (from which the word was derived). But the public does not notice how the antivivisectionists misrepresent facts, nor does it perceive how statistics are distorted by such tricks as that of confusing general mortality with cause mortality, whilst the appeal to sentiment quickly reaches the tender spot in a race which justly prides itself on its humane treatment of dumb animals. Thus the mischief spreads, the benefits of research are belittled, and scientific investigators are represented as heartless tormentors of defenceless creatures. Every medical man knows that if the public were properly informed as to the way in which experiments are conducted and the magnificent results they have achieved the antivivisectionists would become as harmless and negligible a section of the community as the modern Jacobites. An animal experiment is not a private enterprise of a narrowly minded scientist; it is by comparison with other methods of investigation only occasionally resorted to in research, and then only when all other known methods of investigation have failed. As the yearly Home Office Reports show, the vast majority of the experiments performed on animals are carried out for the protection of public health, and we all, just and unjust, reap the benefit of these unadvertised activities. These facts the Research Defence Society makes it its duty to declare to the world. This society was founded in 1903, under the presidency of Lord Cromer, "to make generally known the value and necessity of experiments on animals, the restrictions imposed on them by the Act of 1876, and the great saving of human and animal lives already obtained by means of such experiments." From lives already obtained by means of such experiments." From the headquarters at 11, Chandos Street, Cavendish Square, reports are sent out to members and associates and distributed to public libraries; the magazine, *The Fight against Disease*, may be obtained through any bookseller or news-agent. Members subscribe 10s. and associate members 5s. a year, and the society is very anxious to increase its membership so that the plan of combating antivivisectionism may be carried out on a larger scale. With these objects all medical men must be in sympathy, for the antivivisectionists of to-day deserve the rebuke that Darwin administered in 1881. "I know," he said, "that physiology cannot possibly progress except by experiments on living animals, and I feel the deepest conviction that he who

wards the progress of physiology commits a crime against mankind." It is hard to understand how the antivivisectionists can regard as villainous and unnecessary such disinterested work as that to which Lister referred when he declared: "I have myself often performed experiments on the lower animals, and if I have been privileged in my professional career to do anything for the good of my fellow men more is to be attributed to these experiments than to any other work in which I have engaged."

THE PHYSIOLOGY OF DIGESTION.

SIR WILLIAM BAYLISS gave an interesting lecture, under the auspices of the Fellowship of Medicine, at the Western General Dispensary on November 6th, when he illustrated by experiment the action of the various digestive juices. He reminded his hearers that the product yielded by the action of saliva alone on carbohydrates was not glucose, but maltose, and that the process of conversion into glucose was completed in the small intestine. At the same time there was evidence that if saliva were allowed to act sufficiently long glucose was eventually produced by its agency alone. The time during which food was ordinarily exposed to the action of saliva was naturally brief, though it might be longer than some had supposed. The enzyme of the saliva could not act in the strongly acid solutions of the stomach, but experiments on rats, with whose food litmus paper had been mixed, showed that food did not immediately become acid in the stomach. After a certain length of time the rats were killed, and on cutting across the stomach it was found that only in the outer portion of the food contents had the litmus become red; in the inner part it remained blue. This suggested that there was an additional time during which the process of converting starch into sugar by the saliva might still be proceeding in the stomach. The action of pepsin in converting the proteins as far as poptones, and the action of trypsin in effecting their further conversion into amino-acids, were demonstrated, and also that pepsin acted only in acid and trypsin only in alkaline solutions. The action of crepsin in separating the small aggregations of amino-acids into their free individual constituents for absorption by the cells was illustrated with the help of the preparation called "creptono." Sir William Bayliss also referred to the action of other enzymes, including the fat-splitting enzyme in the pancreatic juice, and the enzyme present in the secretion of the walls of the small intestine, which reduced cane sugar finally into glucose and fructose. The chief function of the bile—to dissolve the fatty acids—was also demonstrated by the use of a preparation of bile salts; by adding alkali the difficulty of the precipitation of the salts in a watery solution was overcome.

THE HARRISON MEMORIAL.

A MEMORIAL, erected by subscription in the rooms of the Chemical Society at Burlington House to the late Colonel E. F. Harrison, C.M.G., will be unveiled by Earl Crawford and Balcarras on the afternoon of Thursday next, November 16th. The memorial, which is the work of Mr. Ernest Gillick, is a bronze relief representing a trench scene at the moment when a gas alarm is given. It will be associated with the roll of honour of the Fellows of the Society who fell in the war. The total amount collected makes it possible to present a sum of over £1,000 to the Chemical Society, in trust for the institution of a money prize, to be awarded every three years to the chemist under 30 years of age who, during the preceding five years, has produced research work judged to be of the greatest merit and promise. Colonel Harrison at the time of his death was Controller of Chemical Warfare at the Ministry of Munitions. He had joined the army in May, 1915, and his technical attainments as a chemist were quickly appreciated. Later on his wide knowledge of his science and his fine character led to his appointment to even more responsible offices, and it is an open secret that still further advancement would have been his had

he not succumbed in November, 1918, to an attack of influenza at the age of 49. Before entering the army, after a very distinguished early career, he was in independent practice as an analytical chemist. It was while thus engaged that he became associated with the BRITISH MEDICAL JOURNAL and undertook the series of analyses of proprietary articles, afterwards collected and published by the Association in the volumes *Secret Remedies* and *More Secret Remedies*. He gave evidence for the Association before the Select Committee on Patent Medicines, and the scrupulousness with which he prepared his case and the transparent honesty with which it was presented made a deep impression on the Committee.

EVIL EFFECT OF EXCESS OF PROTEIN IN MATERNAL DIET.

THE effect on the offspring of the diet of the nursing mother is very clearly illustrated by some investigations recently made by Miss Gladys Hartwell, D.Sc.¹ She has shown that in rats, when the mother received certain typical diets, definite curves could be obtained for the rate of growth of the litters. For example, when the mother was given a good diet of bread and whole milk the young rats at the end of lactation weighed twice as much as when the mother received a poor diet consisting of bread only. It was observed also that when an excess of protein, such as caseinogen, was added to the standard diet of the mother the litters did not fare so well; they lost weight, some suffered from spasms, and many died. Further investigation showed that this detrimental effect of protein² followed the administration of odestin, blood and egg albumen, gelatin, and home-made gluten; such dietaries containing excess protein apparently rendered the milk poisonous and finally checked its flow. The mother suffered no ill effects from the excess protein diets, and Dr. Hartwell found in some cases that there was greater danger to the offspring when the mother gained in weight and flourished on this protein diet. Since the objection might be raised that these results were being obtained on a diet deficient in some accessory factor, Dr. Hartwell has repeated her experiments,³ taking particular care to supply the nursing mother with butter, yeast extract, and lemon juice, thereby supplying ample amounts of the requisite vitamins. The same remarkable disturbances in the health of the offspring were found when excess of protein was added to physiologically perfect diets for the mother. If such a diet was begun before or during gestation none of the young survived; if started at birth, some survived but they were not normal, and the majority died. Until the eleventh day no defect could be observed, but about that time spasms commenced, the convulsions appearing at approximately the same period irrespective of the length of time the mother had been fed on the excess protein diet. This excess protein diet appeared to be excellent for the young rats when they began to eat for themselves, and a large number of experiments have shown that such a diet is adequate for growth, fertilization, and reproduction in the rat. These toxic symptoms could be prevented by the addition of large quantities of whole milk to the maternal diet, but, although the offspring under such circumstances did not develop convulsions, they did not show such good growth curves as litters raised by mothers not receiving excess protein. Large doses of commercial yeast extract added to the excess protein diet also prevented the onset of spasms. In more recent work shortly to be published Dr. Hartwell has shown that the addition of any substance containing large quantities of vitamin B, notably egg yolk, tomatoes, carrot juice, and potatoes, prevented the toxic symptoms developing in the offspring. It is remarkable that a diet apparently so satisfactory for the mother should yet be so disastrous for the young. The constant character of the spasms and the regularity and punctuality with which they are produced point to the excretion in the milk of some

¹ *Biochemical Journal*, vol. xv, No. 1, 1921.

² *Ibid.*, vol. xv, No. 5, 1921.

³ *Ibid.*, vol. xvi, No. 1, 1922.

highly toxic substance; the fact that the disorder can be prevented by the administration of large quantities of vitamin B proves that an error of metabolism must be the underlying cause. If similar results are observed in other animals, it would seem as though another disease must be added to those known to be due to dietary disturbances.

SIR WILLIAM RAMSAY.

A MEMORIAL to Sir William Ramsay, one of the greatest of British chemists, was unveiled in Westminster Abbey by the Duke of York on November 3rd. The memorial, the work of Mr. Charles L. Hartwell, A.R.A., is a profile bust in bronze set in a marble frame, on the base of which is inscribed "William Ramsay, Chemist." The memorial was offered to the Dean and Chapter by the Duke, who was acting for the Prince of Wales; it was accepted by the Dean, who said that it would be added to the galaxy of memorials to scientists which had been set up in the north aisle. The persons so commemorated included Darwin, Wallace, Lister, Adams, Stokes, Joule, and Hooker. To these, the Dean said, was now added the name of the most famous chemist of our century. Among those present were the French Ambassador, the American Ambassador, the Belgian Ambassador, the German Ambassador, the Japanese Ambassador, the Spanish Ambassador, and the Chilean, Danish, Greek, Lithuanian, Netherlands, Swedish, Chinese, and Norwegian Ministers. Sir Charles Sherrington, President of the Royal Society, Sir T. Gregory Foster, Provost of University College, London, where Sir William Ramsay was professor for many years, attended, as well as representatives of the Universities of London and Sheffield. The French Académie des Sciences was represented by Professor H. L. de Chatelier. The Ramsay Memorial Fund, begun in 1917, consists of nearly £58,000, raised by private subscription all over the world; and the capitalized value of the additional endowments by Dominion and foreign governments is as much again. Eleven Ramsay Fellowships, each of the annual value of at least £300, enable promising research students from Canada, France, Switzerland, Greece, Italy, Norway, Sweden, Denmark, Spain, Holland, and Japan to carry on work in any selected chemical laboratory in Britain. There are also British Ramsay Fellowships, including one specially connected with Glasgow, Ramsay's *alma mater*. From the remainder of the Fund £25,000 is being devoted to a laboratory of chemical engineering at University College, London, where Ramsay taught and worked for twenty-six years; there, also, an annual Ramsay medal has been founded. Ramsay's name will be for ever associated with the discovery of the family of inert gases—argon, neon, helium, krypton, and xenon. Argon was the first of his discoveries, and he was led to it by the late Lord Rayleigh's observations on the discrepancy between the density of atmospheric nitrogen and that prepared from compounds. Helium had been presumed to exist on the strength of stereoscopic examination of the spectrum of the sun's chromosphere in 1868, but it was not until 1896 that terrestrial helium was proved by Ramsay to exist. It was in that year that Becquerel of Paris discovered the radioactivity of uranium; Rutherford later on showed that radioactive emanations were inert gases of the argon type, whereupon Ramsay took up the study of the radium emanations enthusiastically. Ramsay from the first had been attracted to the physical side of chemistry and found a congenial sphere of work in the borderland of physics and chemistry, which by the researches we have mentioned he did so much to map. He was a man of most attractive character, beloved both by his fellow workers and by students. He died on July 23rd, 1916, after a long illness which from the first offered no hope of recovery.

MEMORIAL TO LIEUT.-COLONEL E. M. WILSON.

A MEMORIAL tablet to Lieut.-Colonel Edmond Munckhousen Wilson, C.B., C.M.G., D.S.O., R.A.M.C., who died in the Queen Alexandra Military Hospital, Millbank, rather more than a year ago, was unveiled in the chapel of that hospital

on November 3rd. Lieut.-General Sir John Goodwin, D.G. A.M.S., in a brief address, paid a tribute to an old friend and brother officer, who entered the Royal Army Medical Corps as long ago as 1881, and served for twenty-three years with honour and distinction, until ill health compelled him to retire in 1904. Wilson served in six campaigns, chiefly in the Sudan and on the Nile, and came home from the battle of Khartoum in 1899 to take up various important appointments in turn at the War Office and Aldershot. For a number of years he represented the Army Medical Service on the Council of the British Medical Association; he had also been president of the West London Medico-Chirurgical Society, and in various ways he did much to further the interests and the benevolences of his profession. As a man he had a host of friends and not a single enemy. No one could for a moment think any evil of him, for he thought evil of no man. The chaplain-general (Bishop Taylor-Smith) then dedicated the memorial, a marble tablet, bearing the name and titles of the late officer and the words, "He devoted his life to the Corps." There was a large attendance of officers, men, and nurses in the chapel for a brief service. Among those present was Major-General Sir William Macpherson, K.O.M.G., representing the Council of the British Medical Association.

THE ASSOCIATION'S WAR MEMORIAL.

THIS issue of the JOURNAL bears the date of the fourth anniversary of the Armistice, which brought the war that began on August 4th, 1914, to an end. The Council of the British Medical Association has decided that the memorial to members who fell in the war shall take the form of a Book of Honour to be placed in the Library, a memorial tablet in the entrance hall, and a small book for issue to relatives, describing the Book of Honour. It will be seen from the Proceedings of the last meeting of Council, reported in the SUPPLEMENT, that Mr. F. G. Hallett, Secretary to the Conjoint Examining Board in England, has generously undertaken, as a labour of love for the profession, to illuminate and superintend the engrossing of the Book of Honour.

THE Ministry of Health has issued this week the final report of the Departmental Committee on the Causes and Prevention of Blindness. The Committee was appointed two years ago by Dr. Addison "to investigate and report on the causes of blindness, including defective vision sufficient to impair economic efficiency, and to suggest measures which might be taken for the prevention of blindness." The medical members of the Committee were Dr. J. C. Bridge, Dr. A. Eichholz, Mr. N. Bishop Harman, Mr. J. B. Lawford, Sir J. H. Parsons, and Dr. James Taylor, and Mr. C. J. Bend was afterwards made an additional member. We shall publish a full account of the report at an early date.

THE next session of the General Medical Council will commence at 2 p.m. on Tuesday, November 28th, when the President, Sir Donald MacAlister, K.C.B., M.D., will take the chair and give an address. The Council will continue to sit from day to day until the termination of its business.

THE International Society of Surgery will meet in London in July, 1923, under the presidency of Sir William MacEwen. The organizing secretaries are Sir D'Arcy Power and Mr. J. E. H. Roberts, F.R.C.S. The society met last in Paris in 1920.

THE eleventh International Physiological Congress will be held in Edinburgh from July 23rd to 27th, 1923, under the presidency of Sir Edward Sharpey Schafer. The treasurer is Professor Arthur R. Cushman, the secretaries are Professor George Barger and Professor Jonathan C. Meakins, and the assistant secretary is Miss Dorothy Charlton, to whom inquiries may be addressed, at the Department of Physiology, the University, Edinburgh. On request she will send particulars of hotels and lodgings.

THE UNIVERSITY OF SHEFFIELD.

THE FIELD LABORATORIES AND PHARMACOLOGICAL DEPARTMENT.

SIR WALTER FLETCHER

OF

MEDICAL RESEARCH AND DAILY LIFE.

THE new Field Laboratories of the University of Sheffield are now working at full capacity, and on November 2nd were visited by a party of panel practitioners in the neighbourhood.

The Field Laboratories were erected last year at the request of Professor Edward Mellanby on his acceptance of the chair of pharmacology in order that his work on experimental rickets and other dietetic problems, which he had been carrying on in London and at Cambridge, might be transferred to Sheffield. The sum already expended on the erection of the buildings and their equipment is £7,000, and towards this the Panel Committee contributed £1,000, thus affording evidence of the living interest of insurance practitioners in scientific research in medicine.

The buildings of the Field Laboratories have been erected in a field rather more than three acres in area, situated on the edge of the moors at an altitude of nearly 1,000 ft. and about four miles from the university and six from the centre of the city. The buildings consist of a series of army huts suitably modified for their various purposes. One of these (60 by 20 ft.) is used as a residence for the caretaker and assistant. Direct access is provided into a second hut, which is divided into three rooms; one is a chemical and histological laboratory, another is used for *post-mortem* examinations, and the third for weighing and preparing the food for the animals. Between the laboratory and the main building which is used for housing the animals there is a store room in which anthracite, sawdust, and chips are kept. The animal house measures 80 by 30 ft., and is divided into three rooms, which lead into one another; these rooms provide separate accommodation for 65 puppies. A second building, about forty yards from the main group, will be erected for isolation purposes and for treating infective conditions, but owing to the lack of funds this has not yet been completed. At their visit last week the party was afforded the opportunity of seeing the experiments now in progress. The majority of these are designed to throw light on the etiology of several well-known diseases. The extraordinary differences in the growth structure of tissues and general activity of the animals produced by small differences in diet were very clearly to be seen.

In an informal manner Professor Mellanby demonstrated the effect of different diets in the production of rickets. A series of dental specimens, which illustrated the work of Mrs. Mellanby on the influence of diet on dentition, were shown also. Most impressive of all, perhaps, were the remarkable effects on the appearance and activities of puppies fed on different diets.

After the inspection the party returned to the university, where, after tea, they assembled to hear an address from Sir Walter Fletcher, M.D., F.R.S., Secretary of the Medical Research Council. The Vice-Chancellor, in introducing Sir Walter Fletcher, in a few words thanked the practitioners for their help and support.

MEDICAL RESEARCH AND DAILY LIFE.

SIR WALTER FLETCHER said that the Medical Research Council was grateful to the University of Sheffield for the unique arrangements made for the research work conducted by Professor Mellanby and his immediate colleagues, but especially was it grateful for the singular generosity which had inspired members of the medical profession in Sheffield to give important financial support to that part of the work which was being done at the Field Laboratories. The Medical Research Council was making a large annual contribution to the work, but its means were strictly limited and it was a very great encouragement to have voluntary support. It was especially encouraging when support was given directly by members of the medical profession. It was not the case of a benevolent millionaire, though he hoped there might be many such, giving a generous donation towards scientific work as to the nature of which he was imperfectly instructed; but it was the case of men who really knew the meaning of the work giving it support.

Grateful as the Council was for that financial co-operation, it was the interest that generosity evidenced which was specially welcomed. Those interested in the advance of knowledge by scientific research work in the field of medicine needed the help of medical men, at every turn, wherever it was a question of making available for the benefit of the public the practical fruits of research work. There were many directions of inquiry in which the laboratory man was helpless unless the man of practical experience of human needs was closely co-operating with him. That co-operation might almost be taken for granted, but the research worker needed also the help of the profession as interpreters to the public. The laboratory man was buried in the laboratory, and little seen by the public. But the doctor went everywhere, and had the necessary knowledge to guide and enforce public opinion—hitherto backward in this country—which was to support research; public interest and knowledge must be moulded and stimulated by medical men.

"I was reading last week," the speaker continued, "that delightful essay by John Brown of Edinburgh upon Sydenham. Writing in the last generation, long before this most recent busy output of pathological and physiological work, he looked into the future and said that the progress of scientific knowledge affecting medicine was going to increase in a manner which would defy all calculation, and he said that it would have the most important effect upon the quality of the medical profession. He prophesied that the office of physician would in a high sense become more difficult than before, because it would require a greater compass and energy of mind—it would be working in a wider field and with finer weapons. Surely that prophecy has been fulfilled, and the medical man of to-day is working with an incomparably greater compass and incomparably finer weapons than his predecessors of only a generation ago."

Sir Walter Fletcher went on to speak on the general topic of his address—the obvious and visible importance of medical research work in the daily life of the community. The ordinary layman, who put himself unquestioningly in the hands of the physician or surgeon, and accepted all the resources brought to bear to help him, was necessarily little aware of the laborious researches upon which those resources, from large measures of treatment down to tiny points of technique, were based. Research workers had difficulty in bringing home to the public how the work they did bore fruit in practical life outside the technical field of the operating theatre or the medical ward. Research work did not get, or until recently had not got, the same public support and encouragement—and gratitude—from Englishmen as it had received, and was receiving, in countries like Germany and America. The Englishman was in some ways paradoxical. He was characteristically kind-hearted; he hated pain, and if pain were presented to him he desired to help it. British charities for the diminution of suffering were earlier, and had been more generously supported, in this country than in any other, and our nursing services have been earlier and better than those of any other country. But the Englishman was not so imaginative as the instructed public of those other nations. If the pain was stopped, or at least if it were out of his sight, he forgot it, and he did not think so deeply of the importance of preventing it for the future. The sums of money given in this country for the removal of immediate pain and immediate disease and suffering were enormous when compared with the trifling amounts offered either by gift or bequest for the scientific research work by which alone secure advances could be made towards the permanent prevention or further palliation of suffering. There were two ways in which the research worker and his work were apt to be undervalued and underestimated. All work which aimed at preventing pain and disease suffered under a conspicuous handicap. The more successful it was, the less obvious the results. If a disease were practically abolished, as for example small-pox in this country, the boon was easily forgotten. "I am just old enough," the speaker said, "to remember what a pock-marked face is like. I should say that very few of the undergraduates in this room know really what I mean when I speak of a pock-marked face. They have probably no vivid visual recollection of that, and yet their grandfathers could remember a time when a girl's chances of marrying were enormously increased if she were not pock-marked." A more recent example was the inestimable triumph of the virtual abolition of enteric fever and its congeners during the late war. It had often been spoken about, but it was already being rapidly forgotten.

In the South African war very many more men died from the bacillus than from the bullet. But in the late war, owing to research work diligently pursued in the interval in the Army Medical Service, the position was exactly reversed, and, for the first time in recorded history, there were more deaths from the bullet or the shell than from disease. Enteric fever was practically negligible in our army, in spite of the incredibly insanitary conditions of most of the fighting area. Had the lesson really sunk home in the minds of the people of this country?

"I noticed quite lately," Sir Walter Fletcher continued, "two war memorials in the same village—one for the South African war, and one close by for the late war, the great war. I noticed with interest that upon the South African memorial there are a few names, a handful of names, of those who were killed by bullet or shell, and then a long list of those who 'died from illness'—which meant enteric fever. Close by was the memorial to those who fell in the great war, unhappily with a much greater roll of names, but not one of those had died from enteric disease. Imagine what it would be if by some magic you could see inscribed, in any given village, the roll of the names of those who would have died but for that research work. The roll of names would be much longer than the mournful roll of those who actually fell, and it would keep alive our debt of gratitude to the men who produced that result. Yet it was only in the last session that more than a hundred members of Parliament voted in the House of Commons in favour of a resolution that no further public money should be spent upon medical research work. More than a hundred members of Parliament voted in favour of Kenworthy's bill, which would preclude for all future time—until it was rescinded, as future generations would rescind it—any similar research work on behalf of the Army, or the Navy, or for any other Government department, or in the universities of the country, supported by public funds."

There was another kind of difficulty. When the fruits of research had been gathered in—and this was especially true of results of research work like much of that done at the Field Laboratories, which touched the practical daily life of mankind—there was a persistent tendency on the part of what was called the practical man to say "Yes, but of course we knew that before; common sense would have told us that." An old saying, which contained a great deal of truth, was that in this country any scientific discovery was submitted in successive stages to three kinds of criticism. In the first stage men said frankly that they did not believe it, that it was untrue; in the second stage that it was contrary to the doctrines of the Christian religion; and in the third that they knew it before. The "knew it before" attitude was very common, especially in the field of medical research.

Of this the speaker gave two definite instances: "When I went from Cambridge to London to begin my present work in 1914, shortly before the war, I met the Minister of the department which is in duty bound to take chief interest in the results of medical research work, and he was good enough to have a long talk with me on the terrace of the House of Commons. And I remember he cheerfully and frankly said to me, 'Well, doctor' (I have never pretended, then or since, to be a doctor)—'well, doctor, I don't hold with research. If we want to stop disease we must give the people better grub and less dirt.' Now that was the considered opinion of a responsible Minister. There is, of course, much truth in what he said, that given 'better grub' and given 'less dirt' disease would be incalculably lessened in this country; and my reply of course was that I entirely agreed—if he could tell me what better grub was and what less dirt was, for I know no way of finding out those two things except by persistent scientific research work."

"As we look back now we can see how clear a guide has already been given us in many directions towards knowing what 'better grub' means, by scientific work only made possible by public expenditure." Of this illustrations were at hand in some of the work in the Sheffield laboratories. The nation ought to be very proud of the studies of vitamins going on so actively, not only in Sheffield but in other centres of research work: proud because the fundamental discovery underlying it all was made in this country. The whole subject, so to speak, had been the almost exclusive property of the English-speaking races. The Americans had actively pursued it, but the Germans, the Austrians, the French—so active in other directions of research work, especially before the war—were still far behind us in this vitally important subject.

The fruitful and practical applications of the work were immediate and obvious. Further knowledge must simplify the process of getting knowledge, but at present such investigations were expensive, because they had to be done slowly, by the use of animals. But they told us about "better grub" for the people. Already, although we were still ignorant, only at the dawn of the subject, although even Professor Mellanby had, the speaker felt confident, no clear idea in his mind when he used the word "vitamins" in regard to their chemical nature or the mode of their action—already there was abundant practical fruit, a circumstance quite unusual in the history of the growth of science: the British housewife could now be advised, and should now be advised by the proper authorities, of the differences to the present and future lives of her children that depended upon whether she gave them butter or margarine; the differences between one kind of butter and another kind of butter; the time for which she boiled the cabbage (that was a matter of very great importance, or might be, to the lives of her children); and whether she should use lard or other forms of fat; other illustrations would be familiar to medical men. It was being said that all that was "known before." It was obvious, some people said, that milk would be better if it came from a cow eating green grass than if it was eating lay in the winter, and so on. Well, if all this was known before those who knew it and concealed the secret were homicidal criminals. Those who had seen some of the experimental work at the Sheffield Field Laboratories would know the tremendous power of control over the bodily shape and bodily health of the animal which relatively minute differences of diet would bring about. And the study was yet in its infancy; much more work was urgently needed; yet it was possible now to look forward confidently to a time when immeasurable benefit could be brought to the populations of our great cities through this work. Yet more than a hundred members of the last Parliament voted against its continuance.

There must have been very few during the war who did not notice, with a good deal of heart sinking, the passage of the Australians and New Zealanders about our streets, with their splendid figures and faces, who did not reflect sadly that these men were of the same bone and blood as ourselves, and yet seemed to be members of a superior race as compared with the ordinary Londoner: if they had come in the same numbers to Sheffield the contrast might have been even more marked. There was a time coming, to work was fairly pointing the way, with a shameful anomaly if the average Englishman was not at least as finely developed in body and face as those men were. "I hope," Sir Walter Fletcher said, "I may live to see the day when beauty again of that type comes back to the faces of the populations of our great cities."

He could not stay to touch upon the interesting new work about the action of light, and the remarkable way in which sunlight or artificial light, falling upon the skin, seemed able to do part of the work done ordinarily by vitamin substances in food. There again the common-sense man said, "Only a fool could ever doubt that sunshine is good for man. We knew it before." That was true, but in our northern island vast numbers of our fellow countrymen lived in smoky cities, and the knowledge of how to supply by appropriate artificial means proper artificial light, and if necessary food—the equivalent of the rich man's holiday time on the Riviera—would work untold benefits to this country. From a purely scientific point of view there was hardly any more interesting chapter in biology than that now opening, which seemed to point to cod-liver oil as being, in some literal truth, bottled sunlight; we might have to depend upon artificial light and artificial conditions of food until the results of the industrial revolution were palliated and we had built Jerusalem again in "England's green and happy land."

"So much," Sir Walter Fletcher said, "for grub. I had meant to say something about dirt, the lessened dirt that my friend thought would do so much for the diminution of disease. But what is dirt? Let us think of the soldiers in the trenches. It was wholly impracticable to say, 'Let them be clean.' It is impracticable to tell a coal miner to be clean. Almost all our industrial population are in a sense waging a kind of warfare where personal cleanliness of the ordinary kind is impossible during the hours of labour. But it was not dirt in the ordinary sense of the word that injured the soldiers. It was not the mud of the trenches. That brought them nothing beyond inconvenience. It did not bring them death unless it was dirt of a particular kind, and only the scientific

man was able to say what were the dangerous kinds of dirt, and how they could be avoided—how scabies could be prevented, which was one of the greatest sources of loss of man-power during the war; how typhus, coming from the soil, could be prevented; how typhus and trench fever could be kept at bay by tracing out the exact mode by which those diseases are conveyed from man to man by lice, where not mere cleanliness is sufficient, but measures which are effective to destroy particular insects. And in the mines of Cornwall it is not dirt which injured the men's health, but over a large district it was hookworm disease, where the particular stage of the parasite entered through the skin, and so spread the infection; and a knowledge of the precise mode of propagation was sufficient to stamp out the disease. Many are the instances of that kind that will occur to everyone here.

"So many of our opponents—because we have opponents, as well as those who are merely passive—the opponents of medical research work are fond of saying that this or that triumph of medical science is the result of improved sanitation. That can be definitely disproved in many instances. But even our drainage, the enforcement and development of our drainage schemes, has throughout been stimulated and guided by a growing precision in our knowledge of the organisms of disease. Even now research is actively in progress, and is still needed. Research is needed into the new process, the activated sludge method, recently installed in Sheffield. It appears to be completely successful, but it is not perfectly understood, and we may be certain that until it is perfectly understood it can never be constantly successful, and there will always be times when something may go wrong without an available remedy.

"I am sometimes tempted to think that the stimulus of research work has driven sanitation too far. Our knowledge as it has grown has, I think, shown that a great deal of the modern plumbing which is insisted upon by various by-laws is really unnecessary, and dates from a time when a mysterious agent called effluvia was supposed to convey disease. I firmly believe that the cost of housing might be cut down in an important way if science were allowed full play, as it is in some parts of America, in the devices which are now used.

"I should not like to leave the subject, especially when speaking in a university, without trying to remove any impression I may have given that I or any other scientific man, or any of the research workers of the country, are thinking all the time of the material benefits they can produce. They have produced those material benefits, and all mankind owes them gratitude, but it is not for these mere additions to our comfort that these men are working, and it is not merely for the practical fruits that, in my opinion, the public support and public money should be given. It is quite unnecessary, in a place of this kind, to point to the value of knowledge for its own sake. In the instances I have briefly touched upon, where I have appeared perhaps chiefly to think of the practical boons conferred, the interest and beauty of the scientific work involved is very great indeed. This kind of work in any civilized nation is needed not only for utility, though Heaven knows that is justification enough, but for its interest and its delight, for our self-respect and for the dignity of man, and, I would add, for our worship. After all, the second great commandment about loving our neighbour cannot be more than an empty sentiment nowadays unless the love takes a practical form, and unless it is free, so far as possible, from ignorance. This scientific work is necessary for the fulfilment of that commandment. It is necessary, too, for the fulfilment of the other great commandment. That consideration has, I think, never been better expressed than by a physician, Sir Thomas Browne. You remember he said: 'The wisdom of God receives small honour from those vulgar heads that rudely stare about and with a gross rusticity admire His works. Those highly magnify Him who by deliberate research into His creatures and judicious inquiry into His acts return the duty of a devout and learned admiration.'"

Sir Walter was heartily thanked for his address on the proposition of Dr. Arthur Hall, seconded by Dr. Forbes, secretary of the Sheffield Panel Committee. In reply, he said: I know that my Council have it in view to ask Sheffield, if I may use so comprehensive a word, to undertake another very important piece of work, and I hope I may take back a favourable answer with regard to that when I return.

SMALL-POX IN LONDON.

THE total number of cases of small-pox reported in and near London during the year 1922 down to November 4th is 62, with 17 deaths; that is greater than in any year since 1904. Reference to the following table shows that this figure is possibly comparable with the 63 of 1891 and with the 66 of 1900. Each of these figures was followed by a heavy outbreak in the following year; the outbreak which appears now to be impending may be further postponed, as it has already been postponed, both by the improvement in public education on the subject of small-pox and by the heightened efficiency of the public health service; but there is no doubt whatever that the present external pressure of small-pox on the one hand, and on the other the negative internal susceptibility to the disease, brought about by the neglect of vaccination, have reached such a point that an adjustment is extremely likely to take place by means of a smart if not a heavy epidemic.

						1921	5	0	2	

The present run of cases began with the disclosure at a consultation on October 27th, 1922, at St. Andrew's Hospital, Bromley-by-Bow, formerly the Poplar and Stepney Sick Asylum, of a case of small-pox in the person of an inmate who had been admitted from the Poplar institution, formerly the Poplar workhouse, on October 24th, 1922. On October 27th a rash appeared on his skin, and he was removed that evening to the small-pox receiving station of the Metropolitan Asylums Board. Vaccine lymph was sent for by special messenger, and vaccination of the immediate contacts was begun the same evening. Revaccination of all of the staff of the hospital has been brought up to date, and nearly all of the inmates have now been revaccinated. The risk of a spread in this institution is minimized owing to this case having been detected on the same day that he became infectious, and to the prompt measures which have been taken.

On the morning following this occurrence—namely, on Saturday, October 28th—consultations were held on certain cases in the Poplar institution, and as a result there were at once certified five cases of small-pox from two of the men's wards. There was thus suddenly disclosed a most serious situation, inasmuch as there was then reason to suspect that further cases of small-pox were scattered throughout the institution. This, in fact, proved to be the case. Apprehension also arose that infection might have been conveyed outside owing to the free ingress and egress of the inmates and staff.

A rapid plan of operations to meet the emergency was at once drawn up, embracing the following main indications: (1) to search for every further existing case; (2) to remove or destroy the infection thus disclosed, by prompt transfer of the patients and immediate disinfection; (3) to protect the contacts as far as possible by vaccination, and to watch for further cases arising; (4) to ascertain the origin of the outbreak.

Various remedial steps, falling under one or other of these main heads, were taken almost simultaneously. All ingress to and egress from the institution was at once stopped. Immediate notice was given to the Poplar Borough Council, the London County Council, and the Ministry of Health.

Vaccine lymph was sent for; removal of the small-pox cases hitherto discovered, and disinfection of infected articles and places was immediately undertaken; and an individual examination of all the persons resident in or nearly connected with the institution was begun. Acting under medical advice these various steps were ordered or sanctioned by the House Committee, whose Chairman was at once on the spot; and as a result of this and of other conferences which took place as occasion required a situation of much gravity was thoroughly well in hand within thirty-six hours from the discovery of the first cases; apprehension for the future occurrence of small-pox within the institution, except for the considerable number of cases already infected, was at an end.

The individual inspection of all persons in the building was a task of some magnitude. The most exposed groups of persons were taken first. At the discovery of the first group of small-pox patients an immediate note had been made of the age, name, original ward or dormitory, date of transfer and to which ward, date of onset of acute illness, date of rash. Many of the inmates were aged and infirm, it being the practice to transfer cases of serious illness from the institution. As soon as the above particulars were had, it was obvious that certain other wards were likely to contain further small-pox patients; and also, from a comparison of the dates of onset and rash of these first cases, it was apparent that they were infected by a common source which certainly had been acting on or about October 13th to the 15th; accordingly inquiry was at once made for a person who had fallen ill about that date and possibly escaped recognition. This person was speedily found; he had fallen ill on October 13th and had had what now proved to be the rash of small-pox on October 15th and had infected some of the above cases, and others which followed. Whence he contracted his disease is not known. He must have been infected on or about October 1st. He was engaged in laundry work, in which occupation he had the opportunity of handling the clothing of recent admissions. It was also noteworthy that some of the cases which eventually came to light were probably infected about October 10th; the whole origin of the outbreak, therefore, is still undetermined.

As a result of these personal inspections there were discovered and sent away for isolation four further cases on October 28th. That evening a plan was drawn up for the medical inspection next morning of every individual in the building by the medical personnel, who were provided with sleeping accommodation in the building by courtesy of the House Committee. Eight more cases were discovered on Sunday, October 29th. Careful medical inspection was maintained from day to day, as a result of which on October 30th 2 more cases came to light, on October 31st 5 cases, on November 1st 3 cases, on November 2nd 3 cases, on November 3rd one, and on November 4th one, making 32 cases in all arising within the institution.

In the original plan of operations the following classes of contacts were drawn up:

1. Other inmates.
2. Inmates discharged from the institution between October 10th and 28th. This list was added later.
3. Medical and nursing staff in attendance.
4. Scrubbers and other attendants.
5. Male porters.
6. Occasional visitors to the wards, such as guardians and chaplains.
7. Various classes of staff, such as engineers, laundry staff, and others.

These had to be listed and the sleeping places ascertained. In this manner four other cases were detected outside—namely, a medical officer who had been acting as locum tenent, a fireman, a laundry hand, and a scrubber. Instant steps were taken to control the infection likely to spread from these individuals, the contacts at once being vaccinated.

Vaccination of the staff of the institution and of the inmates was begun the same evening (Saturday, October 28th) and was pushed with such energy that by the evening of Sunday, October 29th, about 900 vaccinations had been performed. The staff and inmates of the institution numbered about 950, and the remaining 50 were vaccinated on the morning of October 30th; four vaccinators were at work. Subsequently some stragglers were discovered and immediately vaccinated.

The cases of small-pox observed fell roughly into four classes. Many of the inmates had mild attacks, their wrinkled and inelastic skin showing papules, vesicles, and pustules which were insignificant and ill developed. Some such individuals, however, developed attacks of the greatest intensity. Several initial rashes of the severe petechial type

were noted, and two patients developed haemorrhagic small-pox in its worst form, their skin assuming a universal dull crimson tint from head to foot, accompanied by marked effusion of the conjunctivae. One of these patients, as is not uncommon in such attacks, stated, in reply to questions, that "he felt beautiful." He died the next day.

Among the staff and others in ordinary health, cases of all grades were well developed, from the mild discrete cases ushered in with a severe "cold," followed by a few insignificant spots, to others marked by initial symptoms of great intensity followed by a confluent rash. The total number of cases in or connected with the Poplar institution up to the end of last week has been 38, with 11 deaths.

At the present time, owing to the thorough steps which have been taken, the Poplar institution is almost free from risk of small-pox to its inmates. Inmates discharged, however, between October 10th and 28th constitute a risk to those outside and to other institutions to which they may be admitted. One such case admitted to another institution was speedily detected.

The alertness and decision with which the Institution Authority acted in this emergency deserves high praise, and may well form an example to others similarly placed.

CONFERENCE OF CREMATION AUTHORITIES.

A CONFERENCE of cremation authorities, convened by the Cremation Society of England, was held on October 26th at the Guildhall, London. The main purpose of the meeting was to discuss the causes that deter people from adopting cremation as a substitute for earth burial; the methods by which information about the advantages of cremation might be spread and its practice facilitated and cheapened; and the appropriate fee for medical practitioners or medical officers of health certifying deaths on form C, under the Home Office regulations. The chair was taken by Sir MALCOLM MORRIS, F.R.C.S., and there were present, in addition to representatives of various London and provincial crematoria, Sir William Willecox, M.D., Dr. Louis Parkes, Dr. Chalmers Mitchell, F.R.S., and Mr. H. T. Herring, Medical Referee of the London Cremation Company.

The CHAIRMAN at the opening of the proceedings explained that this was intended to be a round-table conference for the exchange of views rather than for the passing of formal resolutions. Almost every speaker touched on the very slow progress which cremation had so far made, and attributed this largely to uninformed sentiment, but in part also to apathy and indecision among those who approved of cremation. It was agreed that the education of the public in what cremation meant, and how it was carried out, must be pressed forward. Representatives of cremation authorities in several large cities spoke of the lack of public interest with which they had to contend, and of the difficulty experienced in making known the advantages of cremation. A Liverpool alderman ascribed the slow progress rather to indifference than to active opposition; although his authority had done everything possible to overcome hindrances due to the formalities imposed by the Home Office the number of cremations in Liverpool was still very small. Dr. CHALMERS MITCHELL in the course of his remarks expressed the view that in an appeal to public feeling it was most important to recognize the psychology of the public addressed. Popular propaganda in this matter should, he thought, be more dialectic.

Cremation and Death Certification.

Sir WILLIAM WILLECOX emphasized the sanitary argument in favour of cremation, and discussed briefly the safeguards now imposed upon the practice of cremation in order to prevent the possibility of concealment of crime. He recorded his belief that the popularizing of cremation was intimately bound up in a much bigger subject—namely, reform of death certification. The present system of death certification, he said, urgently needed revision; much more care and detail ought to be required for ordinary certification; under a perfect system concealment of crime would be impossible. Mr. HERRING also dwelt on the importance of pressing for reform of the present lax system of death certification. In view of public indifference to hygiene, he thought that propaganda should dwell rather on the aesthetic than on the sanitary aspect of cremation. He added some practical suggestions for dealing with the question of the fee for medical certificates for cremation. Dr. PARKES expressed the view that cremation would not get much farther forward until the medico-legal questions, especially that affecting concealment of crime, had been settled. He agreed that the position of death certification in this country was most

unsatisfactory, and declared that successive Governments had neglected their duty by failing to bring about reform. Provided the medico-legal difficulties were overcome, he could see no reason why arrangements for cremation should not be undertaken as a public measure by municipal authorities.

An informative discussion came to a close with a decision that the conference should be kept in existence to meet again on future occasions.

THE GENERAL ELECTION.

Of the fifty-seven members returned to the House of Commons on Saturday in the absence of any opposition two are members of the medical profession. Sir William Whitla, who again represents Queen's University, Belfast, was President of the British Medical Association in 1909, and has not ceased to give the Association his support both in and out of Parliament. Sir George Berry is returned as one of the members for the Combined Scottish Universities, in succession to Sir Watson Cheyne, who did not seek re-election. Sir George Berry is consulting ophthalmic surgeon to the Edinburgh Royal Infirmary, and has been President of the Royal College of Surgeons of Edinburgh. Sir Henry Craik, also returned as one of the members for the Combined Scottish Universities, represented the Universities of Glasgow and Aberdeen from 1906 to 1918, when the combined constituency was formed and he was elected one of the representatives. He was for many years associated with the Education Department, and from 1885 to 1904 was Secretary of the Scottish Education Department. His constituency probably contains a larger number of medical men than any other. He has exhibited a keen appreciation of the aspirations and needs of the medical profession, has shown his willingness to consult the British Medical Association, and has on many occasions cogently placed the views urged by the Association on behalf of the profession before the House of Commons.

ENGLISH AND WELSH UNIVERSITY CONSTITUENCIES.

At Oxford the representatives in the late Parliament, Lord Hugh Cecil and Sir Charles Oman, both described as Unionists, have to defend their seats against Professor Gilbert Murray, Regius Professor of Greek, described as a Liberal. At Cambridge, Mr. J. R. Butler (Independent), secretary of the Board of Historical Studies, is standing against two Conservatives, Mr. J. F. P. Rawlinson, K.C., and Dr. W. R. Sorley, Professor of Moral Philosophy. For the single seat of the University of Wales there is a triangular contest between Sir E. J. Ellis Griffith, K.C. (Liberal), Mr. T. A. Lewis (National Liberal), and Dr. Olive Wheeler (Labour), who is not, we believe, a member of the medical profession. These contests, therefore, have no direct interest for the medical profession. It is otherwise with those for the representation of the University of London and for the Combined English Universities.

University of London.

For the single seat of the University of London there are three candidates—Sir Sydney Russell-Wells, M.D. (Unionist), Professor A. F. Pollard (Liberal), and Mr. H. G. Wells (Labour). Sir Sydney Russell-Wells, M.D., whose candidature is approved by the British Medical Association, is standing as a Conservative. He was for twelve years Chairman of the University Council for External Students and was elected vice-chancellor in 1919, a position he resigned recently. He is physician and pathologist to the National Hospital for Diseases of the Heart. He looks upon the position of University members as exceptional, since they are not so closely bound by party ties as other members. He is opposed to any attempt to erect two universities in London; and desires that the University should retain its full autonomy and freedom from Governmental control or departmental interference. The Government should help with funds by way of block grants, and not for specific purposes, grants in the latter form being less useful and more extravagant. With regard to health matters he says:

"The health of its people is rightly the concern of any Government. Much has been done, but much more can, I believe, be done without increased expenditure. The present system of overlapping and competing local authorities is both wasteful and confusing. The existing medical benefits under the National Health Insurance Acts should be continued, and should as now be controlled by publicly elected bodies, though the present Insurance Committees are capable of improvement; but the benefits are incomplete and require supplementing by consultant, specialist,

and expert pathological assistance, and in many instances hospital treatment. The establishment of a whole-time and State salaried medical service would, however, in my opinion be a disastrous step, for it would in the long run be very costly; it would minimize the personal and friendly relationship between doctor and patient, and would encourage constant official interference and standardized methods which, in an imperfect and constantly progressing science like medicine, would have a sterilizing effect. War conditions have increased the number of woman medical practitioners, and in all medical appointments no discrimination should be made in emoluments on the ground of sex. Improving the education and widening the knowledge of the medical profession are probably the greatest aids to the health of the community, and increased grants to universities for teaching and research are therefore in this respect, as in many others, a sound investment and true economy."

Professor A. F. Pollard, who is standing as a Liberal, is Professor of English History and Chairman of the Institute of Historical Research in the University of London; previously he was Professor of Constitutional History at University College. He also observes that a university franchise is a privilege grounded upon a special qualification of intellectual attainment and has to find its justification in its results. In dealing with the question of economy, he says:

"There is no source of wealth comparable to the health and brains of a people, and expenditure on those first conditions of national welfare is the soundest kind of saving. There is no economy in disease, and ignorance is the prolific parent of waste." He recognizes that "with a national debt ten times as great as that before the war we have not the means that we had to spend on social reforms, and waging war on private enterprise will not conduce to thrift." Every kind of expenditure is not waste. "Prevention of disease, the building of houses that are needed for living and not for luxury, the improvement of transport, the education of the people are necessary economies, and the fact that we are poor is all the more reason why we should make a remunerative investment of what we have."

Mr. H. G. Wells is a candidate on behalf of the Labour party. He is best known as a novelist, but is a Bachelor of Science, was for some time a secondary teacher, taking the diplomas of Licentiate and Fellow of the College of Preceptors, and has written popular educational books.

In his address he says that he would "battle against the violence of wild men with 'axes' chopping busily at the endowment of knowledge and the health and education of our people." "I am opposed to all this 'axe' mischief in the sphere of public health, education, and research. . . . Let us get on with scientific research and teaching, with education, with production, the development of international controls and world disarmament."

Combined English Universities.

In the Combined English Universities there are six candidates for two seats. The late members, Mr. H. A. L. Fisher (N.L.), until recently Minister of Education, and Sir Martin Conway (U.) are standing again. They are opposed by two other Unionists, Mr. W. B. Faraday, LL.B. Manchester, and Dr. Sydney C. Lawrence, who graduated M.B., Ch.B. Birmingham in 1903; their appeal to the electors is based partly on the fact that each is a graduate of one of the constituent colleges and that it is desirable that the University should be so represented. An independent candidate has come forward in the person of Mr. John Strong, Professor of Education in the University of Leeds; he anticipates a large measure of support from teachers who are graduates of one or other of the universities. The sixth candidate is Mr. L. S. Woolf, who is standing in the interests of the Labour party.

COUNTIES AND BOROUGH.

To the list published last week of twenty-eight medical candidates for the representation of counties or boroughs we have to add three names. Dr. Leonard Molloy, who is a candidate for Blackpool in the Conservative interest, is consulting physician to the Victoria Hospital, Blackpool, served as a combatant in the Duke of Lancaster's Own Yeomanry during the war, and received the distinction of D.S.O. for his services. He is opposed by a Liberal. Dr. C. Harvey Dixon of Oakham is standing as a Conservative for the Rutland and Stamford Division of Lincolnshire, where he is opposed by two candidates, one described as belonging to the Liberal party and the other as an agriculturist. Dr. R. Dunstan is standing in the Labour interest for the Ladywood Division of Birmingham against Mr. Neville Chamberlain. Dr. H. B. Brackenbury, who stands as an Independent Liberal for East Wiltshire, is well known to the members of the British Medical Association, for he is Chairman of the Insurance Acts Committee and has been deputy chairman of the Representative Body since 1921. His candidature has the official approval of the British Medical Association. He has to meet a Conservative, who was until

the dissolution the sitting member, and a Labour candidate. Dr. D. F. Toild, who is a member of the Association and at one time active on its Council and committee, is opposing the late member, Mr. J. J. Lawson (Labour), in the Chester-le-Street Division of the County of Durham. The profession will wish him success.

England and Wales.

LIBRARY OF THE BRISTOL MEDICO-CHIRURGICAL SOCIETY.

We mentioned three weeks ago (October 21st, p. 767) that the Bristol Medical School had been completely incorporated with the University of Bristol. We are now able to announce that the Bristol Medico-Chirurgical Society has presented its library to the University, and that the gift has been gratefully accepted by the Council of the University. The collection comprises over 15,000 volumes, and has been valued at over £12,000. It contains some rare books, and over 100 current periodicals are received in exchange for the *Bristol Medico-Chirurgical Journal*, which is published by the society.

RADIOLOGY AND ELECTROTHERAPY: THE MANCHESTER MEETING.

As briefly announced in last week's issue, a joint meeting of the Röntgen Society and the Electrotherapeutics Section of the Royal Society of Medicine will be held at Manchester, in the Physics Department of the University, on Friday and Saturday, November 17th and 18th. On the Friday afternoon short papers and demonstrations will be given by Professor W. L. Bragg on "The structure of metals as analysed by x rays," and by Professor A. V. Hill on "The psycho-galvanic reflex" and "The hot wire sphygmograph." At 5.15 p.m. Professor Jacobaeus, of Stockholm, will lecture in the clinical theatre of the Manchester Royal Infirmary on "Cauterization of pleural adhesions under fluoroscopic control"; concurrently, Mr. J. R. Clarke will lecture on "Measurement of high voltages," Mr. E. G. McKinnon on "Storage batteries," and Mr. V. E. A. Pullin on "Examination of metals." In the evening there will be a dinner, at which Professor Jacobaeus will be the guest of the evening, supported by Sir Humphry D. Rolleston, P.R.C.P., President of the Röntgen Society, and Dr. Robert Knox, President of the Electrotherapeutics Section of the Royal Society of Medicine. On the Saturday morning arrangements have been made for visits to the works of the Ford Motor Company and the Metropolitan Vickers Electrical Company, in Trafford Park, and other important industrial undertakings, and to the Radium Institute, and the X-ray Department of the Skin Hospital. In the afternoon, at 2.30 p.m., the new X-ray and Electrical Department of Manchester Royal Infirmary will be opened by Sir Humphry Rolleston, and thenceforth the new department will be open for inspection. The meeting is open to non-members, and any medical practitioner who wishes to attend any of the meetings or the dinner will be welcomed; further information regarding arrangements may be obtained from Dr. A. E. Barclay, the Royal Infirmary, Manchester.

MIDDLESEX HOSPITAL WAR MEMORIAL.

The war memorial at the Middlesex Hospital Medical School in memory of those students who lost their lives in the great war has, after careful thought, taken the following form. In the hospital chapel four stained-glass windows have been erected, and the architect of the chapel, Mr. Frank L. Pearson, has made an appropriate choice of subjects by selecting for these windows four soldier martyrs—St. George, St. Alban, St. Martin of Tours, and Joan of Arc. The main part of the memorial to the fallen students is in the medical school. Memorial tablets have been placed in the old entrance hall, and the common room has been panelled in oak and a portrait of Captain John Fox-Russell, V.C., M.C., painted by Mr. Ronald Gray, has been placed in the central panel. The dedication and unveiling ceremony took place on Wednesday, November 1st, All Saints' Day. The Bishop of London conducted the service in the Chapel, which was attended by the Earl of Athlone, many members of the Board of Governors, the chairman of the medical school, Mr. S. G. Asher, the dean of the medical school, Mr. A. E. Webb-Johnson, the chairman of the memorial committee,

Mr. Comyns Berkeley, members of the staff of the hospital and school, relatives of the fallen, Surgeon Vice-Admiral Sir Robert Hill, K.C.B. (Medical Director-General, R.N.), Lieut.-General Sir John Goodwin, K.C.B. (Director-General, A.M.S.), and a large number of past and present students. After the ceremony in the chapel and the dedication of the windows by the Bishop of London those present proceeded to the medical school, where Sir Robert Hill, on behalf of past and present students, invited Sir John Goodwin to unveil the memorial tablets. He remarked on the large number of the fallen who had served in the R.A.M.C., and the conspicuous service the Directors General of the Army Medical Service had rendered by the way they had mobilized the medical profession for war service. Sir John Goodwin made a sympathetic reference to the services rendered by the students of the Middlesex Hospital. Of the forty-six who had fallen and whose names were inscribed on the memorial tablets, eighteen had served in the Officers' Training Corps previous to the war and by the sacrifice of their leisure had been available as trained officers when war broke out. He remarked on the fact that of the forty-six killed fifteen were holding permanent commissions in the R.A.M.C. Conspicuous among these, though only an example of the gallantry shown by all, was John Fox-Russell, who lost his life in the campaign in Palestine, and was awarded the Victoria Cross—

"For most conspicuous bravery displayed in action until he was killed. Captain Fox-Russell repeatedly went out to attend the wounded under murderous fire from snipers and machine guns, and in many cases where no other means were at hand carried them in himself although almost exhausted. He showed the highest possible degree of bravery and valour."

Sir John Goodwin concluded his speech by expressing admiration for the noble sacrifices which had been made, and stated that the sacrifices would be a source of pride to the Middlesex Hospital Medical School for all time. He then unveiled the memorial tablets, which were dedicated by the Bishop of London, and opened the new common room.

THE WELSH NATIONAL MEDICAL SCHOOL.

An appeal is being made to the county councils of Wales to undertake to contribute a sum equal to a rate of one-eighth of a penny towards the Welsh National Medical School. At the meeting of the Brecon County Council last week the Finance Committee recommended that the council should agree to make the contribution on condition that all other county authorities in Wales and Monmouthshire did the like. Two amendments were moved, one proposing that a grant should be made unconditionally, and the other that the council refuse to make a grant under any conditions. Both amendments were rejected and the recommendation of the Finance Committee adopted.

Scotland.

MEDICINE AND CREDULITY.

PROFESSOR EDWIN BRAMWELL delivered his inaugural address as Moncrieff-Arnott professor of clinical medicine in the University of Edinburgh on October 30th. Principal Sir Alfred Ewing, who presided, said, in introducing Professor Bramwell, that they were welcoming the distinguished son of a distinguished father. The subject of Professor Bramwell's address was "The progress of medicine and the retarding influence of incredulity."

After briefly reviewing the history of the progress of medical knowledge, he said that all advance had been founded upon observation and a correct appreciation of the relationship of cause and effect. Mysticism, superstition, and an undue veneration for authority had been the chief factors which from time to time had retarded progress. Various forms of mental healing were popular at different periods, and yet, if the general public only knew it, these were merely adaptations of psychotherapeutic measures which physicians were constantly employing, and the results obtained were no more striking than those obtained by the physician. The difference, however, lay in the fact that medical men applied their treatment with intelligence and did not advertise their cures, while the unqualified practitioner, who depended upon advertising for success, reported his cures and made no mention of his failures. The influence of the press upon

public opinion was far greater to-day than ever before. While the medical profession recognized that for the most part the press was doing all it could to further the progress of science and of medicine, no one would deny that some of the daily papers were largely responsible for perpetuating that spirit of credulity which was so detrimental to the public interest. It was obvious that competition among newspapers was responsible for this state of affairs.

The association of the Church with medicine had been of the closest from the earliest days. To affirm that the deepest religious conviction was compatible with the highest scientific attainment was to admit a fact which was universally acknowledged. Doctors recognized that the minister of religion might be their most trusted ally. All who believed in the existence of a Creator would agree that both the possibilities of scientific progress and of treating disease were dependent upon the will of God. No doubt the minister would be right were he to say that this was not sufficiently realized by the patient. When the minister, as he often did, impressed the patient with this fact and at the same time strengthened the patient's faith in the ministrations of the doctor, he was doing a inestimable service to the cause of medicine. When, however, he proceeded to analyse causes and effects in so far as they had any relation to the practice of the healing art, then, Professor Bramwell ventured to believe, with all due deference, the minister was entering a province for which his training did not fit him.

THE ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A meeting of the Aberdeen Medico-Chirurgical Society was held in the Society's Hall on October 26th, when Dr. Scott Kiddell delivered his presidential address on "The records of the Aberdeen Medico-Chirurgical Society from 1789 to 1922, with some recollections, recommendations, and reflections." He explained that in process of preparation certain sections of the address dealing with the early history of the society, of its association with the infirmary, and of its relations with the medical schools and universities of Aberdeen, had expanded so considerably as to preclude the possibility of oral delivery at one session. The address had therefore been recast, largely added to, and put in permanent form, so that the members might have a complete narrative at their disposal. A copy of the published history of the society—an illustrated book of some 150 pages—was handed to each member after the address. Professor Marnoch expressed the thanks of the society to the president for his interesting address and for the trouble he had taken in preparing and publishing a history of the society as a record of its work and influence during the past hundred and thirty-three years.

At the first business meeting, held on November 2nd, Dr. J. S. Anderson of the City Hospital, Aberdeen, read a paper on "Meningismus." After a brief historical note he mentioned the difficulty arising in the diagnosis of certain cases which show pyrexia associated with severe cerebral symptoms, such as headache, mental dullness, or even head retraction and coma, and he urged the necessity for co-operation with the laboratory in the diagnosis. In meningismus cases, where the cerebro-spinal fluid was said to be normal, the laboratory supplied the essential criteria. These were (1) transparency, (2) no increase of globulin as tested by the Noguchi method, (3) power to reduce Fehling's solution, (4) absence of precipitation in the colloidal gold test, (5) a cell count of five cells or less per cubic millimetre. In an analysis of 25 cases of meningismus Dr. Anderson referred to the underlying diseases, the incidence among children of school age and under, and the symptoms. He considered that Kernig's sign was occasionally present in cases other than uraemia, and that the uncertainty regarding its presence was due to differences in the method of eliciting it. Comment was made on the excellent prognosis and the immediate benefit obtained by lumbar puncture, repeated if necessary; a urea estimation of the cerebro-spinal fluid should be made in any doubtful case. The paper was discussed by Professor Ashley Mackintosh, Sir Henry Gray, and Drs. Cruickshank, Souter, Richards, Skinner, and Colt, and on the motion of the president, Dr. Anderson was cordially thanked for his interesting paper.

The Joint Hospital Scheme for Aberdeen was considered, and it was unanimously agreed on the motion of Dr. Scott Kiddell, seconded by Professor Ashley Mackintosh, that the society express approval of the proposed Burnside-Foresterhill site.

SUSPECTED FOOD POISONING.

The Scottish Board of Health has received from Mr. Bruce White, B.Sc., of the Pathology Department of Bristol University, the report on his examination of the materials sent to him in connexion with the case of suspected food poisoning that occurred at Roswell, Midlothian, in September last. It will be remembered that three children of a farm labourer were affected in this outbreak, and that the youngest child, a girl aged 3 years 10 months, died, the suspected cause of the illness being tinned pears. The materials sent to Bristol were subjected to exhaustive bacteriological examination, but no positive evidence that the illness was due to direct bacterial infection has been obtained. On the contrary, the evidence was strongly against the presence of any such primary infection. This, however, does not preclude the possibility of the illness being due to the activity of toxins of bacterial origin.

Ireland.

ULSTER MEDICAL SOCIETY.

The opening meeting of the session of the Ulster Medical Society was held on November 2nd in the Medical Institute, Belfast. The retiring president, Dr. R. Hall, introduced his successor, Professor R. J. Johnstone, M.P., who took the chair. The President then proposed a hearty vote of thanks to Dr. Hall for his conduct in the chair; this was seconded by Dr. Colville, and passed with acclamation. In his inaugural address the President made sympathetic reference to the deaths during the year of four Fellows—Dr. Brice Smyth, of Belfast, the father of the profession in Ulster; Dr. St. George, of Lisburn; Dr. Wilson, of Castleblayney; and Dr. Washington Tait, of Downpatrick. He then dealt with the subject of his address, "Some aspects of pain in gynaecological practice." Complaints of pain, he said, were ever present in the doctor's ears; its constant recurrence, its variations in the same patients; the same kind of pain apparently arising from diverse causes, all rendered judgement difficult. Films were thrown on the screen showing the nerve supply of the female organs, and the sites of the referred pain in different diseases. Professor Johnstone said that the ovary was often blamed when it was innocent, and escaped censure when it was guilty. Pain was considered ovarian, but examination or operation had revealed chronic faecal accumulation in the caecum, cervical erosion, a stone in the ureter at pelvic brim, or adhesion to a coil of intestine. If the tissue of the ovary was slowly distended, pain was absent, but if the distension was rapid, as by haemorrhage into a cyst, pain was marked. Other causes of true ovarian pain were mentioned, and Professor Johnstone said that his experience was that it was seldom or never necessary to remove both ovaries in entirety, always some healthy tissue was found. The uterus was most tolerant; it could be torn, displaced, bent without pain; and cancer of the cervix was also free till adhesions formed or glands enlarged. In the later stage of cancer there should be no quibble as to free exhibition of opinion. Dr. John Campbell, M.P., proposed a cordial vote of thanks to the President for his address; such a paper proved the great advance in diagnosis and treatment that had taken place in the last thirty years, and the broad and scientific base on which they were built; Dr. Thomas Houston seconded.

The President welcomed Major-General Gibbard, D.D.M.S. of the Irish Command, who was present at the meeting. Dr. John Campbell drew attention of the meeting to the selection of Sir William Whitla as candidate for the Imperial Parliament, and asked those who were entitled to sign the nomination paper. A special general meeting was held immediately after the opening meeting. The Honorary Treasurer, Dr. Turkington, made a statement on the finances, which showed a deficit each year for the last few years. The Council recommended that the subscriptions should be raised 50 per cent. This was proposed by the Honorary Treasurer and seconded by Dr. W. Burns. Dr. Lee proposed and Dr. Robin Hall seconded that the original subscription be retained for members for two years after their graduation. Dr. Renton, Dr. Ritchie, and Dr. J. R. Davison also spoke, and Mr. Mitchell offered to join in a fund to clear off the deficit. The original proposition as amended was passed unanimously.

LIMERICK CITY HOME HOSPITAL.

At a recent meeting of the Limerick medical practitioners in connexion with the proposal of the Health Committee to

dispense with the services of the two visiting surgeons, the following resolution was passed:

"We, the medical practitioners of Limerick, have learned with surprise that it is proposed to dispense with the services of the two visiting surgeons to the Limerick City Home and Hospital, and to replace them by a junior resident doctor. We protest very earnestly against this change as involving a great injustice to two gentlemen who have for more than twenty years efficiently and faithfully discharged their duties to this institution; and also a great injustice to the poor, who will be thus deprived of the services of those very experienced practitioners; while to ratepayers any saving effected will be so trifling as to be absolutely negligible. We would point out that it is quite illegal for any medical man who is not an apothecary to compound the prescription of another."

Correspondence.

THE DOSE OF THYROID.

SIR,—My attention has been drawn by my pharmaceutical colleagues to the dose of dry thyroid gland which is given in the *British Pharmacopoeia* as 1/2 to 4 grains. Physicians using the gland in hospital practice generally prescribe it in this form, which is dispensed in the hospital; and it is in this way that students obtain their knowledge of the dose and uses of thyroid.

In private practice the gland is given almost always in tablet form, and the dose is weighed as fresh gland, which represents only about one-fifth of the dry gland. That is, if the physician orders 1 grain of thyroid gland the patient receives 1/5 grain of the *British Pharmacopoeia* thyroïdonum siccum.

I have reason to know that misunderstanding of these facts has occurred.—I am, etc.,

Cambridge, Nov. 7th.

W. E. DIXON.

INSULIN AND DIABETES.

SIR,—The General Statement of the Physiological and Therapeutic Effects of Insulin, published by Professor Macleod in the *JOURNAL* of November 4th, leads me to place on record certain results of work with which I have been engaged for the past three years. The full particulars of this work I hope to publish shortly. Some of the provisional conclusions that I had reached were set forth in a lecture which I delivered before the Birmingham Branch of the British Medical Association a year ago.

It is now established that, in normal animals and man, after the ingestion of glucose by the mouth there occurs a definite transitory increase in the sugar of the blood, the extent of which may be fairly accurately determined by repeated estimations of the blood at short intervals before and after the administration of the glucose.

It occurred to me that it would be interesting to ascertain whether the extent and duration of the normal alimentary hypoglycaemia could be modified by intravenous injections of a boiled and filtered watery extract of the pancreas which conceivably would contain Cohnheim's substance.

For the purpose of experiment I chose rabbits. The blood sugar curve was determined after 10 grams of glucose had been introduced into the stomach by a tube. A week later with the same animals I determined the curve in exactly similar conditions except for the intravenous injection of a small quantity of the extract. The result was very striking, for the alimentary hyperglycaemia which was very definite in the first experiment was entirely absent in the second. I confirmed the result with other rabbits, and none of these animals suffered any apparent ill effects.

The next step was to conduct a similar experiment on a normal man, and inasmuch as my colleagues at the General Hospital were doubtful if such an experiment was justifiable I injected the extract into my own vein, and obtained a considerable flattening of my normal blood sugar rise after a dose of 50 grams of glucose by the mouth. Subsequently I had a headache and felt ill for a few hours, but so far as I know the injection had no ill effect. I next injected the extract intravenously in a diabetic after a standard test-meal, having previously determined the response of the blood to this meal. In this case I obtained a slight fall in the hypoglycaemia, but the effect was in no way comparable in degree with the fall obtained in my own case. In this patient I later injected the extract several times in one day, but only succeeded in reducing the hyperglycaemia slightly. She complained of severe headache and of feeling ill, but recovered her usual state of health in a few hours.

About this time a rather startling fatality occurred in one of the laboratory animals, and I was led to conclude that the doubts of my colleagues as to the propriety of human experi-

ment were sound, and I felt I had discounted my own malaise and my patient's evident illness after the injections a little too lightly.

Dr. Hillier, at the General Hospital, at this stage very kindly undertook to examine the pancreas of different animals in order to discover the distribution of the islets of Langerhans with a view to obtaining a more potent extract of the islets by using only those portions of the pancreas in which they appeared more numerous. It is worth while recording that Dr. Hillier and I found that our crude extract, which produced such remarkable effects on intravenous injection, was quite inert *in vitro*.

About this time I had the opportunity to investigate the effect of intravenous injections of other substances than the crude pancreatic extract I had been using. In a patient undergoing treatment for asthma I found a lowering of the curve after an intravenous injection of peptone. I have since found that salvarsan intravenously and even T.A.B. vaccine limits the normal alimentary hyperglycaemia after 100 grams of glucose in some patients.

I came to the conclusion that the results that I had observed after the injections of pancreatic extracts were non-specific. For this reason, until I have had an opportunity of examining the controls practised by the Toronto School, I shall reserve my judgement of the ultimate value of insulin. The crucial test will be that of clinical experience.

It would take too long adequately to discuss the significance of the curious fact that injections which flatten the alimentary curve in a normal person only very slightly reduce it in the case of a diabetic. I have had no experience of work with animals after pancreatectomy, but I still remain a little sceptical after fairly extensive reading of the literature whether the condition of animals after that operation is exactly equivalent to the extraordinary variety of conditions in man which are collected under the name "diabetes."—I am, etc.,

Birmingham, Nov. 7th.

A. P. THOMSON.

THE OBJECT OF INVESTIGATION AT THE ST. ANDREWS CLINICAL INSTITUTE.

SIR,—From the notices that appear in the medical and lay press there is some danger that our modest enterprise here may become fashionable before it is understood. Some teachers tell us that they have been doing for a long time what we are attempting, in that they have kept in touch with the out-patient department and taught students the early symptoms of disease. I have been engaged in the study of these early symptoms for over thirty years, and if I were asked to teach students this subject I would decline, for the simple reason that my knowledge is too scant.

Medicine is to-day so befogged that it cannot see the path of progress nor understand its own limitations. A consideration of the state of knowledge on some subjects and a glance back over the course which medicine has pursued may reveal where it has gone astray. In the middle of last century the study of diseased organs, as revealed on the post-mortem table, attained such importance that pathology was assumed to be the foundation of medicine. It was imagined that the nature of ill health and the cause of death could be found there. In consequence of this physicians began to search for the signs of damaged organs during life, and so laid the basis of that diagnosis by physical signs which has ever since dominated clinical medicine, and thus diverted attention from the real cause of ill health.

No doubt pathology is of great value, but the mistake lay, as happens so often in medicine, in expecting a subject to yield a kind of information which it is not capable of doing. The examination of a dead body may reveal a damaged cardiac valve or an inflamed lung, but these are not the causes of death, nor do they account for the symptoms of the antecedent ill health.

The body is maintained in health by the harmonious working of all the organs. Each organ possesses a mechanism which regulates its function, so that the organ is able to meet the ever-varying demands made upon it by the conditions of life. It is the disturbance of this mechanism which provokes the condition of ill health and leads to death. The damaged organ, and particularly the impaired function of the organ, may occasion this disturbance of the regulating mechanism, thus producing the symptoms of ill health or causing death. The change in the organ itself is only an agent which may originate the disturbance. In the same way ill health due to microbial invasion is not due to the microbe, but

to the disturbances set up by the microbe or its toxins. When we reflect upon the great expectations raised by the introduction of bacteriology, and consider the meagre results it has achieved in the elucidation of the diseases common among the people, we will find the cause of this failure to be that bacteriology has devoted itself entirely to the study of the supposed agent of disease, and not at all to the disturbed processes which constitute the disease. This, perhaps, will be better realized if we consider the question of the danger of chloroform anaesthesia. The examination of the body after death has failed to throw any light upon the question. The great number of investigations by "experts" of various sorts—singly and in groups—have failed to indicate the nature or source of the danger. The reason seems simply to be due to the fact that chloroform acts by disturbing the processes concerned in regulating the function of organs, and medical knowledge has not advanced so far as to enable anyone to appreciate the nature of these processes.

If this aspect of the subject is grasped it will be at once apparent why the numerous investigations into medical problems so frequently fail. Indeed, on the same grounds one can forecast with certainty the failure of most projects that are being attempted to-day.

Progress depends more on recognizing the cause of failure than on the contemplation of success. One great cause of the failure of medical investigation is that investigators undertake the solution of the problem without realizing that they have not the requisite knowledge. It wants no prophet to foretell that an enterprise which requires knowledge of a certain kind will fail if it be undertaken on the assumption that that knowledge exists when it does not exist. This is the reason of the failure in many, if not in all, of the wrecked enterprises with which the path of medicine is strewn.

In the enterprise we have set ourselves we have taken the first step—the recognition that we do not yet possess the knowledge necessary for its achievement. Our present duty is to train and educate ourselves. We see that before we can detect and appreciate the significance of the early symptoms of disease we must know the mechanism of those symptoms. We have gone so far as to recognize that most symptoms are due to the disturbance of that mechanism which regulates the function of the organs, and we are endeavouring to understand this mechanism. It is a field of knowledge which is to all intents and purposes unexplored, for we find the knowledge lacking which would enable us to understand the nature and significance of the simplest symptom—such as, for instance, the mechanism of an increase in the pulse rate, of a cough, of nausea, of vomiting, of pain. Hitherto the profession has contented itself with the idea that as much of these symptoms was known as was necessary for practical purposes. So long as this delusion prevails no progress can be made.

An inquiry into the mechanism of this process, which regulates the functions of organs, how it is disturbed, and the agents that cause the disturbances, is the object of our investigations at present. What further steps will have to be taken are at present hidden from us. But of this we are assured, that until this kind of knowledge is acquired there is no prospect of the real problems of disease ever being solved.—I am, etc.,

St. Andrews, Fife, Nov. 2nd.

J. MACKENZIE.

X RAYS IN HYPERTRICHOSIS OF THE FACE.

SIR,—Having read Dr. H. C. Semon's letter in your issue of November 4th, I cannot help feeling that he has said both too little and too much. Too little, inasmuch as he gave no details of the technique employed as regards filters, dosage, and exact frequency of application; too much because, though the case he refers to was treated presumably in accordance with the imperfect technique of eleven years ago, he applies his generalizations to present-day methods. I do not dispute that his deductions may be right, but if the same method of reasoning, and the adage, "*primum non nocere*," had been applied to various medical and surgical modes of treatment of many diseases a dozen years ago, would not both medical and surgical progress have been retarded? It is by trial and error that we progress.

Twelve years ago many leading engineers and physicists said heavier than air flying machines were impossible. To-day we know they were wrong. Twelve years ago Dr. Frank Schmitz of Berlin condemned the x-ray treatment of hirsuties. Last year Dr. Thurston Holland said nothing would induce him to treat hirsuties with x rays, and both were men of

great experience; but for 2,200 odd years we considered Euclid infallible till Einstein came. And so it may be again. I have been carrying on the active practice of x-ray treatment for only sixteen years, and so will not venture to dogmatize any more than Dr. Semon. Still, it is helpful if the least of those amongst us contributes his quota of experience and judgement.

Ten years or more ago I had the misfortune, while treating tinea tonsurans, to cause permanent alopecia on a number of heads without any immediate or subsequent dermatitis. During the past five years I have treated over 1,000 cases of the same sort without failure either way. The beard is, of course, quite a different proposition; still it is difficult to see why, if permanent alopecia can be accidentally produced on the head without bad results to the skin, it cannot also be induced in the beard likewise, and I believe it can. During the last seven or eight years—before I had Erlangen apparatus—I had to administer post-operative prophylactic irradiation to several adult male patients with various malignant conditions about jaws, mouth, and tongue, and my method was to treat once a fortnight, giving 1 B pastille dose measured through 3 mm. of aluminium, about twenty such doses being given. In each case I produced permanent alopecia of the beard over the treated areas, and in none have any atrophic changes appeared on the skin, which is soft, elastic, and of normal colour.

Applying the same technique to hirsuties in young females I have obtained similar results, although sufficient time has not yet elapsed to guarantee that no telangiectasis will follow. In each case I warned the patients of the risks, and they were willing to take them. Hypertrichosis in a young and pretty girl is a very serious condition as it tends to become a bar to marriage and has led sensitive natures to suicide. I think therefore we must make every effort to find a remedy. They all abhor the idea of shaving—which is really the safest and best remedy—chemical depilatories by congesting the skin only make the growth of hair stronger, and electrolysis, besides being only a partial remedy, disfigures the face as much almost as x-ray atrophy. In the early days of x-ray therapy, when we had no proper mode of measuring doses, when our tubes were all too soft as a rule, when we treated too frequently, thereby producing a summation of doses sufficient to induce erythema, and when we used no filters, nearly every case developed atrophy. We then had ample opportunity of studying this terrible condition. Since the introduction of aluminium filters I have found telangiectasis follow the use of a 1 mm. filter frequently; I have also seen it follow a 2 mm. filter though much less frequently, but although I treat many thyroids in cases of Graves's disease I have not yet seen telangiectasis follow through a 3 mm. filter.

To sum up, then, my view is that hirsuties treated at monthly intervals through a 3 mm. filter, or preferably a 4 mm. filter, giving 4/5 B to 1 B doses on a London pastille, and giving up to twelve to fifteen treatments, good and safe results may be obtained.—I am, etc.,

Bradford, Nov. 4th.

WILLIAM MITCHELL.

ALLEGED FAULTS IN MANUFACTURE OF NEO-SALVARSAN AMPOULES.

SIR,—One fatality and some toxic phenomena having been observed in the Lock Hospital in Cairo, some of the salvarsan ampoules were banded to us for investigation. The tubes were suspected to be faulty and to have allowed decomposition of the contents, for the following peculiar but interesting reason. On immersing the tube in alcohol the contents became sticky and adhered to the glass, and it was thought that this meant that alcohol had penetrated into the interior of the ampoules. We verified the statement as to stickiness, but we further observed that this condition of stickiness did not appear till after withdrawal from the alcohol and then only lasted a brief time, after which the contents became as powdery as before. It seemed clear that there must be some special physical explanation of this very peculiar phenomenon, for there were certainly no holes in the capsules. The phenomenon was found to be exaggerated when ether was used in place of alcohol. This gave the clue to the mystery. We immediately plunged the ampoules in ice and found that the powder in them again adhered strongly to the glass even more than with alcohol or ether. We had already found that the contents of the ampoules were under reduced pressure.

The explanation of the phenomenon is therefore as follows:

On removing the ampoules from alcohol or other the surface evaporation cools the ampoules just as they are directly cooled by the ice. In all three cases the cooling increases the vacuum, especially of the spaces between the particles of the light powder, and the powder and the walls of the ampoule; doubtless this is because the glass and the solid powder conduct and absorb heat more quickly and to a greater degree than the air within the ampoules. The particles of powder once brought together by the contraction of the imprisoned air now adhere by cohesive force until shaken apart. That the phenomenon only occurs with certain powders is probable. It is also possible that traces of vapour within the ampoules may be deposited as dew on the particles and on the walls of the vessel and aid cohesion, but this would not be easy to prove. The important fact, however, and the one to which we desire to draw attention, is that the explanation lies in the contraction due to cooling, and the phenomenon is purely physical and may be repeated at will; it does not in any way show the capsules to be unsound. On the contrary, it probably only occurs when the capsules hold a partial vacuum. Although anyone looking at the capsules when quickly cooled would almost assuredly assert that the powder was wet, this is not the case. After a few seconds' standing and shaking the powder looks dry again. Examination of the ampoules for toxicity revealed no special potency of this preparation as compared to other bateses.

We think these observations worthy of record because we have not heard of a similar report, and certainly at the time of the accidents due to the injections the suggestion that the cause lay in faulty ampoules caused much alarm. We also think the observation may be of interest to manufacturers, because it might again happen, as it certainly has happened here, that many a medical man would think the manufacturer at fault and get his preparation elsewhere. The thin ampoules show the phenomenon best because they so readily respond to the cooling, and thus neo-salvarsan put up in thick tubes appears drier than that in the thin tubes. In our samples the French neo-salvarsan of Poulenc Frères was in thin capsules and the German preparation in thick. As we have shown, there is no ground for the idea that the ampoules were at fault in any way.—We are, etc.,

EDMUND CHARLES GRAY,

Government Medical School, Cairo,
Egypt, Oct. 17th.

THE RADICAL PREVENTION OF VENEREAL DISEASE.

SIR,—I for one cannot agree with the recent letters of Dr. Herbert Caiger. What is needed is a clean-cut understanding of our line of action, and when the subject is crystallized out it resolves itself into one of discretion only. A man is wise for himself.

Dr. Caiger's disparaging remarks about the administration of Moses shows a lack of humility, as if we had improved on his system of government. Circumcision was not instigated to prevent venereal disease, though it lessens the risk. There was probably no syphilis in the time of Moses, and this alone made it more evident that other deterrent influences should operate. Dr. Caiger complains of the use Moses made of fear in establishing an A1 nation, and in "doing justice to St. Paul" he seems to think there was no fear in St. Paul's teaching. How comes it, then, that a man "must work out his own salvation with fear and trembling"?

What, then, are our means by which we can prove our friendship towards the youth of the nation? Shall we preach indulgences and recommend appliances and disinfecting agents, and so call evil good? By these means we might possibly, but not probably, stamp out syphilis, but the remedy would be a hundredfold worse than the disease, inasmuch as it would lead to a universal physical weakness and degeneracy unparalleled in history. We should then be under the obligation of stamping out the means itself, for mental as well as physical abnormalities come under our sphere. Shall we show reckless disregard and allow a nation to become thoroughly syphilized? This would lead to a worse degeneracy, and although the fear of syphilis would disappear on account of the loss of its virulence, other fears of a worse type would take its place.

Neither of these methods is admissible, although most of us would rather see a youth escape even though he escaped

by the means of those who preach indulgence. But considering there is more than enough indulgence, why need this be preached? It is enough in the interest of knowledge to barely mention it, but to strike out the fear of consequences is to lead for the day of calamity.

We are therefore left with the only one safe method—discretion—and our only weapon is fear. The windy doctrines of morality and patriotism take no hold on youth. In teaching youth discretion it is well to try to recollect that we were once young ourselves, and to recall to mind the special proclivities and early causer in even the fairest of flowers. The hereditary uprightness is more marked in youth than in age, when faith tends to become weak and idols strong. Fear, therefore, has more terrors and is consequently more powerful. The fear of a broken spirit, the clipped wings shutting off the vista of future happiness, sinks more into the heart of youth than any amount of proffered mythical fruit of modern towers of Babel. Who are they who have pulled through? The discreet ones, those whose teachers have struck fear into their hearts, medical students (caught young) and ambulance men who have dusted with calomel the condylomata of others, and those who have taken heed to the acceptable words of sensible men.

In rebuking youth, as in rebuking anyone else, the rebuke to be of any good must be terrible. Hard words are not necessarily unkind words. The sting of the rebuke must be directed against those whom it is intended to benefit, not against the cause, so that justice may be tempered with mercy.—I am, etc.,

Huddersfield, Oct. 31st.

T. DOBSON POOLE.

SIR,—I am interested to read the letter by Mr. E. B. Turner in your issue of October 23th. I lectured to the soldiers and officers at the Tooting Grove Military Hospital, but not to such a great number as he refers to.

I certainly could never see any reason for appealing to their patriotism, as I considered that they had shown this in volunteering to go to the front and risking their lives, when we had so many who were trying to avoid service abroad by various means. It was natural that these men, full of virility, should, owing to the slackness of the authorities, contract disease. The Government took no steps whatsoever to protect these young men. I am certain that if the diseases had been made notifiable and all sufferers isolated the number of cases would have been considerably reduced. As it was not a notifiable disease the authorities were unable to deal with the cases of men who wilfully, maliciously, and of aforethought spread the disease.

About 10 per cent. of the officers at Tooting Grove did not appear to be very anxious to get well, and during their sojourn in the hospital, and while under treatment and the disease in an active state, they broke bounds and spread their complaint among the residents in the neighbourhood. When this matter was brought before the colonel of the hospital he had no method of dealing with it satisfactorily, and referred the cases to the G.O.C., who came down and gave a lecture to the officers, in which he stated that he knew that none of them would forget they were officers and gentlemen and would stoop to such a thing as spreading infection, but at this time he had had brought to his notice the names of over fifty officers who had committed this offence.

The fact is there was no law to deal with the matter, the diseases not being notifiable. Some of the most patriotic men in the world have contracted these diseases. In fact this class of man is the most liable to err in this direction.

I am certain there is only one way of stamping out these diseases, and that is by dealing with them as we have with other contagious diseases. If the number of innocent victims who got infected year by year were known I am certain that public opinion would compel the authorities to act in this matter.—I am, etc.,

London, W., Nov. 4th.

JOHN ARMSTRONG.

SIR,—In the BRITISH MEDICAL JOURNAL of October 28th (p. 827) my friend the enemy of self-disinfection, Mr. E. B. Turner, protests against the inference conveyed in my letter in your issue of October 21st, that numbers of men deliberately allowed themselves to be infected with venereal disease to escape the firing line.

My reply in detail is:

1. *British Troops*.—In August-September, 1917, over 5,000 troops came on leave to Paris, and 1,038—over 20 per cent.—became infected, no calomel tubes being issued; but when calomel tubes

who issued and prophylactic lectures given from November 8th, 1917, to March 31st, 1918, and nearly 30,000 troops were on leave in Paris, the medical officer in charge stated that the venereal disease rate had been reduced to only 3 per cent., and that, "of this 3 per cent., it was ascertained by questioning the men personally that . . . one-third wanted to contract venereal disease because they preferred to be in hospital to being in the front line."

2. *American Troops*.—Venereal disease was quite well recognized as a self-inflicted disease among the American troops, and orders were issued warning officers to watch for "wilful infections"—sometimes sought for trivial reasons, such as obtaining a change of command (vide *Manual of Military Hygiene*, issued by American Red Cross, 1918). For example, p. 20: "Requisites of treatment of venereal disease:—1. Soldier treated in his own unit to save postage; 2. To treat the soldier as far as possible in his own command lest venereal disease be made a convenient excuse to escape military duties."

3. *English Prostitutes*.—Diseased women on the streets of London and elsewhere offered sexual intercourse to soldiers at a higher price because of being diseased. The Canadian, Australian, and New Zealand authorities made special reports to the British Government on the matter, and tried without avail to get these women isolated.

4. *English Soldiers*.—During the war English soldiers were reported for buying and selling tubercle sputum and venereal discharge, and in other ways seeking different forms of self-inflicted diseases. Some men wilfully infected their own eyes, not knowing they would become blind.

These facts can quite well be verified by Mr. E. B. Turner in the proper quarters—namely, in the experiences of Army commanders, medical officers in charge of venereal disease isolation hospitals, general hospitals, casualty clearing stations, convalescent camps, etc. Among our soldiers there were many saints and more heroes who can rightly claim our highest love and admiration; but alas, there were also many frightened men, worn-out men, mad men who committed cowardly and antisocial acts, yet for whom, nevertheless, those of us who really know war have only an infinite pity.—I am, etc.,

London, Nov. 2nd.

ETHEL A. ROOT.

POST-GRADUATE COURSES.

SIR,—I am a member of the post-graduate class now enjoying a series of clinical demonstrations at the Royal United Hospital, Bath, and a notice of the work being done may be of interest.

The medical staff of the hospital have arranged a series of six demonstrations: they are open without fee to all practitioners, and the attendance of the two so far held has been very good, some thirty medical men of the city and the country round being present.

At the first class, cases of lymphadenoma and pernicious anaemia were shown and a short clinic was given on these cases and a case of splenic anaemia which had been successfully operated on; the spleen and films of blood from the different cases were then shown by the pathologist, who also gave a demonstration of blood grouping tests. Then a blood transfusion in a case of pernicious anaemia was done in the theatre.

At the second clinic a gastro-enterostomy was performed and a case operated on for gall stone; each operation was preceded by a short lecture. The pathologist then showed methods of examining stomach contents, and afterwards x-ray photographs of stomach and bowel were shown.

The remaining clinics are to deal with kidney, heart, nervous, and orthopaedic cases, and with any other cases of surgical or medical interest that may occur.

The staff most hospitably provide tea at the end of each meeting. That the greatest interest is taken in these lectures by everyone present is obvious, and one cannot but realize what a profound effect this sort of course must have not only on the work of each medical man but also on the whole medical service of the neighbourhood, including insurance service and the hospitals.

How much this sort of thing must do to make general practice more interesting and enjoyable those who have long practised without this advantage are possibly the best judges, and as one of them I felt it would be but bare justice and gratitude to give some idea of what is being done.—I am, etc.,

October 30th.

A RUSBY G.P.

PERIODICITY OF GNAT BITES.

SIR,—It is a matter of common observation that the site of a gnat bite is subject to recurrent irritation at periods of twenty-four, forty-eight hours, etc.

Allowing that the primary irritation increases local vascu-

larity and so aids the insect to get her fill of blood, it is not so clear how, or why, the subsequent irritations occur.

May I ask for any information which can elucidate the subject?—I am, etc.,

Ringwood, Hants, Oct. 25th.

WM. OLIVER BEDDARD, M.D.

Obituary.

LEOPOLD GEORGE HILL, M.D. DUNELM., M.R.C.S.,

Physician to the Church Missionary Society.

DR. LEOPOLD HILL, whose death took place in London on October 26th, was a student at the London Hospital during the late eighties and early nineties. He obtained the M.R.C.S. and L.R.C.P. diplomas in 1893, and the M.D. degree of Durham University in 1911.

Dr. C. F. HANFORD writes:

Leopold Hill was one of a large body of students at that period who were led to see, in a manner which has hardly been repeated since, the imperative call of medical missions. It is difficult to interpret the meaning of those movements which affect certain periods of history, and without inquiring too closely into the influences which specially brought Hill to his decision, yet one who was practically a contemporary can trace something of the inward secret of this remarkable period. In the first place, there was the new realization of the meaning of Christianity and the spiritual life which was associated with the work of two humble Americans, Moody and Sankey. They succeeded in showing to the young people of that day that the Christian religion was not a mere matter of forms and ceremonies but a vital force which could not only transform individual lives but the world.

The most sensational development of that period was the going forth of "the Cambridge seven," a band of leading athletes headed by C. T. Studd, perhaps the best all-round amateur cricketer of his day. The same spirit touched the medical schools of this land, and one who fanned the flame of enthusiasm and directed it into most useful channels was the late Dr. J. L. Maxwell, formerly a Presbyterian missionary in Formosa, and a real leader of men. Hill, like others, came under Maxwell's influence, and his sound common sense led many to see that medical missions demanded a good all-round medical training as a partner to the missionary spirit, both of which are essential to the making of a medical missionary.

The London Hospital received a considerable number of those who were definitely preparing for this special service, and Hill was a popular and particularly well qualified man who emerged from that band of students. Hill offered his services to the Church Missionary Society, and was fortunate in being assigned to Pakhoi in South China, where he was associated with Dr. Horder, who already had organized a well-equipped hospital and leper asylum. In the development of this Hill took a prominent part, and the influence of the hospital affected a very wide area, while the leper work was of a particularly high order. South China has been fortunate in securing the services of a series of eminent medical practitioners in its varied centres, Manson and Cantile having been among the number, and Hill took his share in the work for the Imperial customs and consular service. On being invalided home in 1904 he took up busy work as a general practitioner in North London, in which he was engaged up to the time of his death. While doing this he held the post of physician to the Church Missionary Society from the year 1911, and worthily maintained the traditions of this great office, which is concerned with the physical needs of about 1,400 individuals scattered mainly throughout the tropics. Hill's careful clinical methods and sympathetic manner earned for him the respect and confidence of the medical board and of the society generally, and he was beloved by all his colleagues.

THE LATE PROFESSOR CRUM BROWN.

SIR JAMES WALKER, F.R.S., Professor of Chemistry in the University of Edinburgh, has been good enough to send us the following brief appreciation of his predecessor: "As Crum Brown's pupil, friend, and successor I am glad to be allowed to add a few lines to Dr. Ballantyne's obituary. The student of medicine who listened to his lectures during a winter session could form little idea of his scientific eminence; to science students his advanced lectures on organic chemistry were a revelation. Philosophical and suggestive, they compelled the listener to think; but it was after all the delightful laboratory talks which constituted the chief feature of his advanced teaching. He was always ahead of the time—even

his thesis written while still a medical student was a decade in advance of the views of the ordinary professor. I have often found that novel theories beginning to attract attention had to me the aspect of familiarity, and this familiarity I could always trace to some conversation I had had with Crum Brown. Had he been tinged in the slightest degree with ambition he would have been recognized as one of the foremost theoretical chemists of the age. As it was, his merits were known to comparatively few, but their admiration of his great gifts is unbounded."

THE death took place recently of Dr. W. F. LITCHFIELD, of Glebe Point, Sydney, at the age of 51 years. He was born in New South Wales, and was educated at Newington College and the University of Sydney, where he graduated M.B., Ch.M. in 1893. He was for three years resident medical officer, and afterwards for more than twenty years honorary physician to the Royal Alexandra Hospital for Children; he was a member also of the Board of Directors. He was president of the Section of Paediatrics at the last Australasian Medical Congress in Brisbane (1920). He was also a member of the councils of the Royal Welfare Society for Women and Children, and of the District Nursing Association; he was honorary physician for the Church of England Homes, Glebe, and a member of the board of directors of the Royal Alexandra Hospital for Sick Children. Dr. Litchfield took a great interest in the work of the New South Wales Branch of the British Medical Association, being a member of the Council for several years, medical secretary, and at the time of his death vice-president. As a young man he was keenly interested in debating societies, especially those at Glebe Point, and in later years was a popular member of the Drummoyne Golf Club. He has left a widow, two daughters, and four sons.

MR. CHARLES HOBHAM EVANS, F.R.C.S., died in London on October 21st. He was the fourth son of the late Dr. Evan Evans, R.N., and was educated at Edinburgh and at University College, London, taking the L.S.A. in 1885, the M.R.C.S. and L.R.C.P. Lond. in 1886, and the F.R.C.S. Edin. in 1912. He filled the posts of house-surgeon at the Miller Hospital, Greenwich, and at St. John's Hospital for Diseases of the Skin; and afterwards was surgeon for out-patients to St. Anne's Hospital. He was a member of the British Medical Association, and a Fellow of the Royal Society of Medicine. He joined the R.A.M.C. in the first week of the war, taking a temporary commission as lieutenant on August 12th, 1914, and was promoted to captain after a year's service.

DEPUTY SURGEON-GENERAL WILLIAM CARDEN ROE, Army Medical Department (retired), died at Bournemouth on October 6th, aged 88. He was born at Boris-in-Ossory, Queen's County, Ireland, on November 30th, 1833, and took the L.R.C.S.I. in 1854. Entering the army as assistant-surgeon on December 1st, 1854, he attained the rank of brigade-surgeon on November 27th, 1879, when that rank was first introduced, and retired on November 11th, 1880, with an honorary step as deputy surgeon-general. He served in the Crimean war of 1855-56, in the 89th Foot, the Royal Irish Fusiliers, and was present at the siege and fall of Sebastopol, receiving the medal with a clasp, and the Turkish medal. According to the Army List, there are now only four medical survivors of the great wars of the middle of last century; one who served in the Crimean war, two in the Mutiny, and one in both.

The Services.

DEATHS IN THE SERVICES.

Lieut.-Colonel Robert Talbot Beamish, R.A.M.C. (retired), died suddenly in London on October 26th, aged 73. He was born at Cork, educated at Queen's College, Cork, and graduated M.D. of the Queen's University, Ireland, in 1873, and M.Ch. in 1874. He entered the army as surgeon on February 3rd, 1878, became lieutenant-colonel after twenty years' service, and retired on April 20th, 1901. He served in the Burmese war in 1886-87, receiving the medal with a clasp; and in the South African war, in the operations in Orange River Colony, where he was in charge of a general hospital, with the local rank of colonel, and received the Queen's medal with two clasps.

Lieut.-Colonel Michael Harris Thornley, Indian Medical Service (retired), died at Epsom on October 30th, aged 47. He was educated at Guy's, and took the M.R.C.S. and L.R.C.P. Lond. in

1897, the D.T.M. Liverpool in 1903, and the F.R.C.S. Edin. in 1910. He entered the I.M.S. as lieutenant on January 27th, 1900, obtained the rank of lieutenant-colonel on July 27th, 1919, came home on furlough preparatory to retirement last year, and actually retired so recently as October 8th last, three weeks before his death. He spent several years on military duty, during which he served in the Waziristan campaign of 1901-2, on the north-west frontier of India, receiving the frontier medal with a clasp. He then entered civil employment in Bengal, and, on the division of that province in 1911, was posted to the newly-formed province of Bihar and Orissa. There for the last few years he was civil surgeon of the important station of Cuttack, the headquarters of Orissa, and also superintendent of the Cuttack medical school and of the Cuttack lunatic asylum. He served in Egypt during the late war.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

At a congregation held on November 4th the honorary degree of M.A. was conferred on H. R. Dean, M.D. Oxon., Professor of Pathology, who was presented by the Public Orator. The following medical degrees were conferred:

M.D.—H. W. Hales.
M.B., B.Ch.—A. A. Prichard.

The Vice-Chancellor has informed the Senate that under the will of the late Sir William Dunn a further sum of £45,000 now accrues to the School of Biochemistry, making a total grant for the purpose of the school of £210,000.

It is announced that the General Board considers it desirable that a University Lecturer in Embryology should be appointed at a stipend of £250.

UNIVERSITY OF WALES.

THE following have passed the examination in Pathology and Bacteriology for medical and surgical degrees:

D. I. Bowen, D. A. Davies, D. T. Davies, *Edith M. Davies, *L. C. Edwards, Ann C. Evans, Marjha Griffith, E. C. James, *T. G. I. James, *L. D. Owen, T. P. Rees, Muriel A. Stephens, W. E. C. Thomas, Constance Walters.
*With distinction.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

Harry Godfrey Massy-Miles Prize, 1922.

At a meeting of the College on November 3rd the Harry Godfrey Massy-Miles Prize for the year 1922 was awarded to Dr. Michael Brandon Devane. Dr. Devane obtained over 80 per cent. of the possible marks in the Final Examination in Midwifery held by the Royal Colleges in March, 1922. The Harry Godfrey Massy-Miles Prize has been established in the Royal College of Physicians of Ireland by Mrs. Massy-Miles in memory of her husband, Captain Harry Godfrey Massy-Miles, M.C., R.A.M.C., a Lieutenant of the College, who died of wounds received in France on April 18th, 1918.

Medical News.

THE joint committee of the Royal College of Physicians of London and the Royal College of Surgeons of England, which administers the trust founded by Mrs. Streatfeild for the promotion of research in medicine and surgery, has appointed Mr. Kenneth M. G. Balloy, M.B., L.R.C.P., M.R.C.S., to be a Streatfeild scholar. The subject of his research is infection of the urinary tract by coliform bacilli; it will be conducted at St. Bartholomew's Hospital.

THE Medico-Psychological Association of Great Britain and Ireland will meet at the Botham Royal Hospital, Lambeth, S.E.1, on Thursday, November 23rd, at 2.45 p.m., when the president, Professor G. M. Robertson, M.D., will give an address on the discovery of general paralysis, from Haslam to Bayle, and Dr. E. W. Scripture will read a paper on the treatment of general paralysis by malaria and the use of speech inscriptions for early diagnosis.

AMONG the members recommended for election to the Council of the Royal Society at its anniversary meeting on November 30th are Professor T. R. Elliott, M.D., Professor G. H. F. Nuttall, M.D., and Professor D. Noel Paton, M.D. Sir Charles Sherrington is again proposed as president, Sir David Prain, M.B., as treasurer, and Mr. W. B. Hardy, lecturer in physiology in the University of Cambridge, as one of the secretaries.

A MEETING of the Medical Officers of Schools Association will be held at 11, Chandos Street, W.1, on Friday, November 24th, at 5 p.m., when Dr. A. R. Friel will read a paper on the ionization treatment of otorrhoea. There will be a demonstration of apparatus used, and also lantern slides. A discussion will follow. All medical practitioners interested in the subject, as well as medical officers engaged in the treatment of otorrhoea at that treatment centre, are invited to attend.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MBI phono, 2 Medical Bacillus.
6. Rutla telephone, 4361, Central.

QUERIES AND ANSWERS.

STIES.

"M. P." asks for hints in the treatment of persistent and recurrent sties on eyelids. He has tried calcium sulphide internally and disinfecting lotion without improvement.

URINE TESTS.

Mr. W. H. MARTINDALE, Ph.D. (London) writes: In reply to Dr. Washington Isaac's inquiry (September 30th, p. 620) about the stoppers of bottles containing Fehling's solution becoming fixed and crystallized, the only satisfactory way to prevent this is to use a little soft paraffin on the stoppers. One could not advocate the use of glycerin in this instance. The same applies in the case of acetic acid and brine used for albumin testing. Another good plan is to employ rubber corks instead of glass stoppers. Furthermore, the amount of reagent required can easily be removed with the aid of a small pipette and test without even touching the lips of the bottles.

INCOME TAX.

"A." sold one-half share in his practice to "B." as from December 1st, 1921. For 1922-23 "A." has been charged on his average earnings over the three previous years and "B." on his earnings for the four months to April, 1922.

* There should be one assessment only on the profits of the whole practice determined by the three years' average profits thereof. The duty chargeable on that assessment is divisible between the partners but payable by the firm. The division should be made by calculating each partner's tax as due on the gross assessment less his personal allowances.

"W. S. W." is a partner in a practice which, since 1914-15, has accounted for income tax on the basis of cash receipts, but the local inspector of taxes wishes to change to the basis of bookings.

* We are of opinion that the inspector's request should be resisted—see a reply to "G. M." in our issue of November 4th (p. 698). The fact that the assessment was on the "bookings" basis in 1913-14 and 1914-15 may be due to special circumstances—for example, it may have been a new practice or may then have but recently changed hands.

"C. W. E." inquires as to the proper assessment of a practitioner entering a partnership.

* Liability is determined by the share of the partnership assessment—on the three years' average basis. Bank interest can be treated as a professional expense, or alternatively repayment can be claimed on the amount of interest paid in the financial year. Instalments of the purchase price are capital payments, and no deduction can be claimed for them. This applies also to the purchase of the original equipment of instruments, books, etc., and to its improvement; any sums spent on maintaining and repairing the equipment can be claimed as a professional expense in determining the average profits.

"W. R. B." has a resident appointment in a Poor Law infirmary and is being taxed on his emoluments.

* It was decided in 1892, in the case of Tennant v. Smith, that emoluments received in kind and not capable of conversion into money were not taxable—the case dealt with a bank

THE Aberdeen University Club London dinner will be held on Thursday, November 16th, at Gatti's Restaurant, at 7 for 7.30 p.m. Dr. Milligan, 11, Upper Brook Street, W.1, will be very glad to hear from any past or present graduate wishing to attend.

THE annual dinner of the London School of Medicine for Women (Royal Free Hospital) will be held at the Holborn Restaurant on the evening of Friday, December 1st.

THE Harben lectures before the Royal Institute of Public Health will be delivered in the Lecture Theatre, 37, Russell Square, W.C.1, by Professor Theodore Madsen, M.D., Director of the State Serum Institute, Copenhagen, at 5 p.m., on Friday, December 1st, Monday, December 4th, and Tuesday, December 5th. The subjects of the lectures are: "Specific and unspecific antitoxin production," "Antitoxic treatment," and "The Influence of temperature on antigen and antibodies." All interested are invited to attend.

A MEETING of the Ilarveian Society will be held at the Town Hall, Harrow Road, Paddington, on Thursday, November 16th, at 8.30 p.m., when Sir J. Thomson Walker will give an address on "Problems of prostatectomy," to be followed by a discussion in which Messrs. Cyril Nitch, Roche Lynch, A. Clifford Morson, J. H. Chaldecott, Montague Smith, and John Macevoy will take part.

AT the meeting of the Royal Microscopical Society at 20, Manover Square, W.1, on Wednesday next, at 8 p.m., Dr. Charles Singer will read papers on the first micubalcal microtome and on the first microscopical drawings.

DR. ANNETT and Mr. M. N. BOST are engaged in experiments on poppy selection with a view to the production of medicinal opium of high quality. As the quantity of opium available from the few plants produced in such selection experiments is not large they have devised a method, which they reported to the meeting of the Society of Public Analysts on November 1st, for estimating the principal alkaloids in small quantities of opium.

THE Council of the Optical Society has decided to hold a conference and exhibition on ophthalmic optics, spectacle frames, and lens construction on Thursday, November 30th, at the Imperial College of Technology, South Kensington, London, S.W. The exhibition is not confined to those of British origin; it will consist of all apparatus, frames, and lenses connected with spectacle fitting and construction. It will be open from 2 to 7 p.m. From 4.30 to 10 p.m., with an interval, papers will be read on the above subjects by ophthalmic surgeons, physicians, and members of the industry. The president of the society is Sir Frank Dyson, F.R.S., Astronomer Royal.

TWO cases of rabies, one in a dog and the other in a cow, occurred in Holland during September, both in the province of Overijssel.

THE first meeting of the session of the Assurance Medical Society was held at 11, Chaudos Street, W., on November 1st, when the president, Dr. R. A. Young, read a paper on the assessment of elderly lives for life assurance. The next meeting of the society will be held on January 3rd, 1923, when Dr. J. Strickland Goodall will speak on the significance of the extra systole.

THE French Government has offered a number of scholarships to Canadian universities, including the Universities of Toronto, Montreal, Laval, and Ottawa. The winner of a scholarship will spend the next academic year in France; the scholarship has a value of 6,000 francs, with an additional 1,000 francs for travelling expenses.

AT a meeting of the trustees of the Warren Triennial Prize at the Massachusetts General Hospital on October 13th it was decided that, owing to the difficulty of determining the relative merits of the first two papers, two prizes instead of one should be awarded this year, the first of 500 dollars and the second of 250 dollars; the second prize was not to be taken as establishing a precedent. The first prize was awarded for an essay on "The circulation in the mammalian bone marrow" by Dr. C. K. Drinker, Dr. Katherine M. Drinker, and Dr. C. C. Lund, of Boston, U.S.A. The second prize was awarded for an essay on "The effect of x rays on the nuclear division" by Dr. J. M. Mavor, of the Union College, Schenectady, New York.

THE thirty-first meeting of the Association of Military Surgeons of the United States was held in Washington on October 12th, under the presidency of Captain F. L. Pleadwell, U.S. Naval Medical Service. Major-General M. E. Ireland, Surgeon-General of the U.S. Army, and Rear-Admiral E. R. Stitt, Surgeon-General of the U.S. Navy, outlined the medical work of the army and navy of the United States. Representatives of the army and navy medical services of Britain, France, Spain, Japan, Peru, and the Argentine Republic were present as guests of honour; Surgeon Rear-Admiral C. M. Beadnell, R.N., and Colonel P. G. Goldsmith, of the R.A.M.C., were the British delegates.

manager's privilege of rent-free residence. We know of no case specifically dealing with Poor Law emoluments, but it would be governed by the House of Lords' decision in the above-noted case, unless the facts are essentially different—for example, if "W. R. B." was engaged at a salary subject to deductions for board, etc., supplied, he would be liable on the full salary and not on the balance paid over to him.

"A. N." has sold a side-car outfit and bought a Morris Cowley car. The allowable expense is the amount that the replacement of the side-car outfit would have cost—that is, £140-£15-£55. "A. N." is apparently assessed for a public salary, under Schedule E, and not for general profits, under Schedule D; technically, therefore, he is not entitled to the allowance unless the replacement was "necessary" and "wholly" effected for the performance of the duties of his office.

LETTERS, NOTES, ETC

SWEATING IN PULMONARY TUBERCULOSIS.

DR. MARCUS PATTERSON (Medical Superintendent, Colindale Hospital, Hendon) writes: Your correspondents will be interested to know that night sweats can easily be prevented without drugs by the use of a Japanese grass mat placed over the mattresses and under the sheet. Such mats are obtainable from Messrs. Mayer and Phelps, New Cavendish Street. An article going into great detail with regard to these slumber sweats was published by me last August in the *Lancet* on page 225. It is interesting to see that both your correspondents have noticed the effect of good hygienic conditions on night sweats—a matter to which I have referred in that article. Dr. Porter's method of waking the patient is a sure but unnecessary method of stopping the sweats. In the article mentioned it states that these sweats should be called "slumber" and not "night," as they may occur at any time when a patient goes to sleep. Waking the patient without even the whisky will surely stop the sweats! I do not agree with Dr. Erie that there is any connexion between the heart and the sweats, except in so far as increased toxæmia may be the cause of the tachycardia. In that case, the tachycardia would be the result of the same condition as that which was producing the slumber sweats.

HERPES AND VARICELLA.

DR. WM. MCCALLIN (Southampton) writes: The following may be of interest to those who are on the look-out for cases bearing on the question of the connexion between chicken-pox and herpes. Sixteen days after the first appearance of chicken-pox in a boy aged 6 years, I saw his sister, aged 1 year and 9 months, who was supposed to have the same disease. The eruption consisted of numerous vesicles with the distribution of chicken-pox, and herpetic patches on the left side of the chest. It has taken the ordinary course of herpes. There have been neither chicken-pox vesicles nor fresh crops.

IS DISQUAMATION AFTER SCARLET FEVER INFECTIVE?

DR. JULES F. REY (Bognor) writes: Many years ago—about 1935—I remember reading of an experiment carried out in Germany where desquamating children from scarlet fever were washed with soap and water and the skin covered with sterile dressings for some days, then the desquamations were collected therefrom, and spread on bread-and-butter and given to children to eat, who had never had scarlet fever. None of them contracted the disease. Secretions from the body are the all-important sources during the first ten days; after this they only persist in chronic inflammations (such as naso-pharyngeal) and sores, however small or where situated. If the child after fourteen days has none of these he is no longer infective, and it is unnecessary to further segregate him. On the other hand, infectivity may be present for a year or more in chronic naso-pharyngitis or any discharge such as otorrhoea. There is recorded an instance where some children played with a skin foot cast (which came from a scarlet fever case ten or twelve years previously and was kept under a glass shade). They developed typical scarlatina a few days later—another evidence of the longevity of the virus in the dry state, for, no doubt, dried secretions were present upon the cast, for there is no mention of the foot having been washed beforehand. The way virulent dry secretions can be conveyed is truly remarkable.

PSYCHO-ANALYSIS.

DR. ARTHUR LYNCH (London, N.W.) writes: I propose to introduce into this discussion considerations which may seem as strange to your readers as those of Pasteur when he first astonished the medical men of Paris by neglecting to talk mediæval nonsense and by proceeding to draw figures of organisms on a blackboard. Similarly what I now state will be subsequently so definitely accepted that future generations will wonder how scientific men could be content to speak in any other form on problems of mental analysis.

If we were to place ourselves in face of the whole world of thought, and if we proceeded by successive operations of analysis to reduce any kind of complex to its ultimate elements, we would find invariably as a result these—as I have called them—fundamental processes of the mind: (1) immediate presentation;

(2) conception of unit; (3) memory; (4) association; (5) discrimination; (6) generalization; (7) feeling of effort; (8) impulse; (9) ideation; (10) sense of negation; (11) conception of time; (12) conception of space. These fundamental processes are, as I have proved by methods of entire rigour, necessary and sufficient to cover the whole field. I may remark that it was the failure to obtain such a mode of demonstration that rendered the psychological systems of Aristotle and Kant defective, and the superstructure which they reared on that psychology, being vitiated by the basic error, became scientifically valueless.

The interplay of these fundamental processes constitutes the mode of action, or the mechanism, of all forms of thought. Dr. Freud shown any analysis of this sort? No. Proceeding from a remark of Charcot, whose own psychology was very inadequate, he catches on to one element—that of association; and then bringing in a heterogeneous mass of observations, supposition, observations, and silly reasonings, he builds up his system. It may be objected that I merely posit my fundamental processes here. Yes, but the complete demonstration will be found in *Psychology, A New System*; and hence I merely quote conclusions. In this book there is no allusion to Freud, but in my forthcoming *Principles of Psychology* I make that reference and overthrow the whole fabric of his nonsense. How? Simply by way of corroboration in a footnote, by showing that it is inconsistent with the scientific principles I establish. Thus, for example, when the principle of conservation of energy is set forth it is laudable to reject every pretended invention that runs counter to it, and that indeed constitutes the only scientific form of criticism.

I will leave discussion of applications till later, only now saying that for years I carried on definite experiments in memory. Freud has nothing of the sort to show. The result is that his discussion of memory is worse than useless, it is misleading, while I have laid down—I speak again confidently for I have brought the matter here also to demonstration—certain laws. (Professor L. Dugas in a recent book, *La Mémoire l'Oubli*, adopts my results as decisive.)

THE ACTING COMMANDING OFFICER DECIDES.

THE *Western Morning News* recently contained a rather amusing account of a court-martial, held at Devonport, to inquire into charge of drunkenness against a naval officer. He had been reported to the acting commanding officer as having come aboard drunk. The commanding officer agreed with the diagnosis. The accused denied that he was drunk and urged that he was wilfully prevented from having the opportunity of calling medical evidence. The commanding officer in defending his action said that he had not sent for the medical officer because he had always understood that if the commanding officer of ship said a man was drunk the medical officer could not reverse his decision. This is an amusing illustration of the view some executive officers take of the extent of their authority, but the point of the story is that the court-martial acquitted the accused.

THE ALVARENGA PRIZE.

THE College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to about 300 dollars, will be made on July 14th, 1923, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays may be upon any subject in medicine, but cannot have been published. They must be typewritten, and written in a language other than English should be accompanied by an English translation, and must be received by the Secretary of the College, 19, South Twenty-second Street, Philadelphia U.S.A., by May 1st, 1923. Each essay must be sent without signature, but marked with a motto and accompanied by a sealed envelope having on its outside the motto and within the name and address of the author. The successful essay or a copy of it must remain in possession of the College; other essays will be returned upon application.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 35, 38, 39, and 40 of our advertisement columns, and advertisements as to partnerships, assistantships and locumtenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 183.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£ s. d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 423, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a cheque or postal order for the amount.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

352. Recent Advances in Neurological Therapeutics.

JEAN CAMUS (*Paris Médical*, October 7th, 1922, p. 297) concludes his annual review of neurology in 1922 by describing recent advances in treatment. Painful cramps in paraplegia "en flexion" have been successfully treated by intramuscular injections of cicutino hydrobromide, the dose being 1 to 3 mg. each day for eight consecutive doses. Almost all the patients experienced rapid improvement, sometimes within three or four hours of the injection. Pain and involuntary contractions of the lower limbs are especially relieved, and patients sleep better. The treatment is successful in different types of spastic paraplegia, whether due to compression by tumour, Pott's disease, injury to the cord, or syphilitic myelitis. The good effects last for four or five days after discontinuance of treatment; freedom from pain may be maintained by further injections (0.5 to 1 mg.) every second day. Pierre Mario and others have compared the results of hypodermic injections of curare (5 to 10 mg.) in similar cases. Curare acts as powerfully and more rapidly than cicutine. The former appears preferable in more severe cases. Calvé has treated severe paraplegias due to Pott's disease by intraspinal aspiration of cold abscess. In three cases he has obtained two cures, and in the other case marked relief. Collewaert has devised re-educative treatment of cases of writer's cramp by means of passive and very gentle active movements, followed by carefully planned writing exercises, the patient sitting at a table of suitable height with both forearms resting on the table and elbows well flexed. Careful modifications of the handwriting to avoid all strain on the fingers, the movements being performed as far as possible by elbow and shoulder, the hand gliding over the paper with minimal finger movements. Camus states that the results of intrathecal treatment are excellent in some forms of meningitis, and he has shown its advantages in tetanus. He has also demonstrated the dangers of intrathecal poisoning by mercurial and arsenical salts, etc. Paullan and Dragesco have injected 1 or 2 c.cm. of 25 per cent. MgSO₄ solution into the cerebro-spinal fluid in cases of chorea with good results. Marinresco confirms this. Camus remarks that similar treatment in tetanus is not free from danger, and its effect is very doubtful. In a number of mental cases—acute mania, general paresis, delirium tremens, and dementia praecox—Urechla has obtained good results from intrathecal injections of isotonic solutions of calcium salts. Marinresco continues to recommend intrathecal injection of salvarsanized serum in cases of neuro-syphilis, but Sicard has seen no beneficial results and considers the treatment dangerous. Auto-serotherapy may produce anaphylaxis, even when the serum has been heated to 55°. Camus states that certain authors have found spirochaetes in cases of disseminated sclerosis a few hours after death, although the Wassermann reaction was negative. He recommends treatment by neo-salvarsan, when the diagnosis is certain. Karl Petren has treated paralysis agitans by combined active and passive movements systematically carried out for a long time. He claims that cases have improved and that progress of the disease has been retarded by this treatment. Rodriguez, however, has seen no improvement result from physical methods, but relies upon sodium nucleinate and eacodylate and scopalamine given hypodermically. Sicard also recommends this treatment in conjunction with massage and Swedish movements. In epilepsy, luminal (gardenal) has been very generally used, but it is stated that it sometimes produces mental torpor and in other cases delirium. The dose should therefore be reduced very gradually and belladonna, caffeine, bromides, and potassium bichlorate, in conjunction with luminal, are recommended. In status epilepticus, bromides, luminal, bleeding, hypodermic injections of scopalamine (0.1 or 0.2 mg.), rectal injections of chloral, and inhalations of chloroform have all been recommended.

353. Hepatic "Anergy" in Tuberculosis.

N. FIESSINGER and P. BRODIN (*Ann. de Méd.*, June, 1922, p. 475) adopt von Pirquet's term "anergy" to describe the disappearance of the normal systemic and local reactions to infective agents; this has been observed in all acute and severe infections, especially in measles and during pregnancy. The authors give details of four fatal cases of tuberculosis in married women, whose ages ranged from 34 to 61 years. All the patients had hepatic cirrhosis, two of the atrophic and

two of the hypertrophic type: the youngest had a positive Wassermann reaction. The autopsies showed old fibrous or fibro-caseous tuberculous lesions in every case, although very limited and undiscovered during life. All four patients were "very clearly alcoholic"; the initial symptoms were rapid emaciation with anorexia, followed by ascites and slight jaundice. Fever and signs of severe hepatic insufficiency supervened. The patients suffered from delirium and hallucinations before death, attributed to chronic alcoholism and severe terminal jaundice. Evidence of acute tuberculous meningitis was present in only one case (the eldest), but all had recent progressive tuberculous lesions. The authors admit the frequency of a terminal acute tuberculosis in hepatic cirrhosis, but consider that their cases do not fall within that category, their view being that the fatal infection failed to stimulate the liver to a protective reaction. The arguments for and against the generally accepted interpretation are set forth at great length with an elaborate description of the pathological findings, followed by details of experiments, which the authors consider are proof of the correctness of their hypothesis—"an organism disarmed and a weapon which fails—the healthy functioning of the liver." Their practical conclusions are: "To treat with care the liver of quiescent cases of tuberculosis; especially to avoid blind overfeeding, that absurd digestive therapeutic measure in which ordinary practice demands the association of toxic drugs—creosote, guaiacol, arsenic, phosphorus, and others more or less in fashion—in that imaginary antiseptic which exists no more in tuberculosis than in any other pathological condition. To forbid alcohol lest it should injure the liver. We shall not go further. 'Hepatic opotherapy' in certain forms of tuberculosis is an experiment only . . . it is one of those indefinite, uncertain therapeutic procedures which, whether followed by favourable or unfavourable results, prove nothing."

354. Oral Administration of Vaccines.

THE possibility of the successful administration of vaccines by the mouth is a question which is exciting a considerable amount of interest at present in France. C. NICOLLE and E. CONSEIL (*Ann. de l'Inst. Pasteur*, August, 1922, p. 579) have just brought forward evidence in favour of the efficaciousness of this method in the case of two diseases so different as Malta fever and bacillary dysentery. In the former case two volunteers received by ingestion a total of 400,000 million dead organisms from a vaccine made up with five different strains of *M. melitensis*. The doses were distributed over a period of five days. After fifteen days they, together with a control volunteer, were injected subcutaneously with 450 million living organisms. On the two vaccinated individuals no effect was produced, while the unvaccinated control developed a typical attack of Malta fever, starting in seventeen days, showing a positive blood culture after thirty-nine days, and yielding in another ten days to the daily inoculation of a *melitensis* vaccine. In the case of dysentery, two volunteers ingested a total of 400,000 million dead *Shiga bacilli* over a period of five days. One of them, with an unvaccinated control, was infected fifteen days later with 10,000 million living bacilli given by the mouth, while the other, also with a control, received 20,000 million living bacilli eighteen days later. In each case the control individuals developed typical dysentery, *Shiga's* bacillus being isolated from their stools, and in each case they were rapidly cured by treatment with antidyenteric serum. The two persons who had been vaccinated, on the other hand, remained perfectly well. These results are quite clear cut, and though the experiments were made on a small scale they certainly have the merit of being performed on human beings and not on laboratory animals.

355. Special Indications and Methods of Administration of Digitalis Preparations.

J. MOLLARD (*Journ. de Méd. de Lyon*, September 20th, 1922, p. 569) condemns the modern tendency to reduce the dose of digitalis—such small doses are useless; it is better to adhere to the dosage of the *Coder*. It has not been demonstrated that the various preparations of digitalis have special indications. It is, however, useful to try different preparations in the treatment of heart disease, in order to discover which best suits the patient's case. The administration of digitalis should be carefully watched on account of its cumulative action. Mollard has seen its effects persist for twenty or thirty days after its administration has been stopped, although generally they disappear in from eight to

twelve days. The author enumerates the official preparations of the *Codex*, and discusses the varying quantities of active principles which they contain. "Digitaline crystallisée is the only one with a definite chemical composition, and a constancy of action on which one can rely." The powdered leaves are particularly unstable on account of intracellular diastases which set up fermentation. After discussing the official doses, Mollard states that, according to Manquat and Fieussinger, these should be three or four times stronger, but he himself prefers the dosage of the *Codex*, and considers that these doses suffice in ordinary cases; but he has never seen bad results following the administration of 1 mg. of digitaline crystallisée in one dose, as advised by Vagnot. The author praises the mode of administration and doses recommended by English writers, and he does not agree with the theory that the extract or infusion is more diuretic than digitaline, but affirms Mackenzie's view that variations in the action of digitals depend more on the nature of the heart lesion than on the preparation of the drug chosen. In cases of "gastric intolerance" of digitals, hypodermic or intravenous administration should be employed, for which purpose the 1 in 1,000 alcohol glycerin solution of digitaline (*Codex*), which is sterile and can be diluted with water without precipitation, is recommended. In urgent cases the daily dose of 20 drops may be exceeded. This method is contraindicated in the last stage of heart failure, nraemia, bradycardia due to auriculo-ventricular "block," and in serious hepatic or renal complications. Mollard concludes by reiterating his remarks regarding the potency of digitals and the need for careful observation of its effects.

SURGERY.

356. End-Results in Cancer.

In a discussion of cancer C. H. MAYO (*Annals of Surgery*, September, 1922, p. 308) points out that the disease selects its victims from the mature and aged rather than from the youth of the nation. The greatest loss from cancer is between the ages of 40 and 60. The sexes are affected in the ratio of three women to two men, the difference being in the organs of reproduction. Environment and, apparently, acids are contributing factors; more than one-third of cancers in men are found in the highly acid stomach; the acid large bowel is often affected, the alkaline small intestine rarely. Views suggested are that regression or degeneration of cells, loss of function, and irritation are factors in its etiology; or it may arise in the immature, waiting, or repair cell. Ochsner believes the cause to be of microbial origin. Chemical environment is undoubtedly a most important stimulating force. The cells of youth are more resistant to cancer, but once affected the results are more serious. Treatment is making great progress. Operations are more radical, whilst radium and x-ray treatment checks the activity of growth if operation is advisable. The action of the rays causes complex physicochemical changes in which the cells become oedematous and nuclear substance breaks down, whilst all powers of cell regeneration are lost; the debris is carried away by phagocytes and replaced by connective tissue. Many early and some late cases have been apparently cured by such treatment. The end-result of x-ray and radium therapy is fibrosis, which often changes the type of malignancy. The probability of the cure of cancer can be largely foretold by the pathologist, depending on the amount of fibrosis present. A very active cellular growth with proliferation, especially if the lymphatics are invaded, is a most fatal type.

357. Scarlatinal Otitis.

W. T. GARDINER (*Journ. of Laryngol. and Otol.*, October, 1922, p. 497) reports results of two years' otological work in the scarlet fever wards at the Edinburgh City Hospital for Infectious Diseases. In 1920-21 10 per cent. of the admissions showed ear complications, and in 1921-22 6 per cent., the otorrhoea commencing most commonly during the first three weeks of the illness, and especially in the first week. Pain is a reliable sign of ear mischief, though it is not infallible, as it may be due to peritonsillar abscess, or even impacted wax, and ear discharge occurs twice as often without pain as with it. It is usually present in the early stages of the first and second weeks, but is seldom complained of from the third week onwards. The discharge is generally purulent and may have a foul odour frequently diagnostic of diphtheria and confirmed by meatal swabs. The tympanic membrane may present every variation of change, from a mild catarrh to a red bulging with obliteration of landmarks, and in the majority of cases the meatus contains desquamated epithelium which syringing will not remove sufficiently to give a view of the membrane. No case of the membrane being destroyed in a few hours, or even in a few weeks, was observed, and in all cases where

a large perforation was noted a history of previous ear discharge existed. Adenoids were diagnosed 141 times in 300 cases, and in some the otorrhoea dried up without operation. As regards early paracentesis, the drum head ruptures so readily that it is impossible to dogmatize, though in favorable cases it was performed within six hours of observing the bulging, and even this was frequently not soon enough, the membrane having already ruptured spontaneously. Conservative treatment consisted of the usual instillation of 1% H_2O_2 and regular syringing. Although otorrhoea associated with adenoids may dry up under such treatment the result is only temporary, and therefore every case of scarlet fever with adenoids, whether otorrhoea occurs while in hospital or not, should have the adenoids removed before leaving, because of the liability for otorrhoea to develop with the first attack of rhinitis acquired afterwards. Five hundred units of diphtheria antitoxin were given before operation, and no untoward occurrence resulted from performing the operation while in the general wards of the fever hospital. Seven per cent. of the cases developed mastoid complications, two types occurring practically equally—namely, (a) developing in the third week of the otorrhoea with pain, tenderness, oedema, and fever; and (b) developing quietly without pain, tenderness, or even fever in the fourth or fifth week. Bone should be removed wide of the apparent disease; in no case was it found necessary to perform the radical or modified radical operation.

358. Resuscitation by the Intracardiac Injection of Adrenaline.

J. GOTTESMAN (*Journ. Amer. Med. Assoc.*, October 14th, 1922, p. 1334) reports the case of a man, aged 73, with generalized arterio-sclerosis, who developed severe pain in the right leg due to trophic changes. The pain continued to be very severe, and on September 20th amputation of the affected extremity under spinal anaesthesia was attempted. The injection of 10 c.cm. of 1 per cent. solution of procain into the spinal canal was followed almost immediately by drowsiness, cyanosis, and shallow respiration. The heart action remained good for about five minutes, when the patient became unconscious, respiration ceased, and the pulse and the heart sounds could not be detected. Artificial respiration was begun and various cardiac stimulants, including caffeine, camphor, and adrenaline, were given hypodermically, but without effect; the breathing had ceased and the heart's action seemed to have stopped. Twenty minims (1.2 c.cm.) of adrenaline, full strength, were then injected into the left auricle by puncture of the chest wall between the left third and fourth ribs, the position in the cavity of the heart having been determined by aspiration of blood. There was immediate reappearance of the radial pulse and of feeble respiratory efforts. This was followed by the return of the heart sounds. The cyanosis was gradually replaced by normal colour, and within a few minutes respiration became regular, the heart's action good, and consciousness was restored. After this the patient made an uneventful recovery from his symptoms.

359. The Treatment of Osteochondritis Dissecans of the Knee.

J. HELLSTRÖM (*Acta Chirurgica Scandinavica*, September 18th, 1922, p. 190) reviews the literature and records in detail five cases of osteochondritis dissecans. The choice of treatment depends on the stage of the disease. If it has already given rise to a free body in the joint operative treatment is imperative. It is also indicated when there are symptoms without the existence of a free body. The choice of treatment is more difficult when there are no symptoms, and the disease is accidentally discovered by the x rays. In such cases it may be sufficient to adopt expectant, conservative treatment, but, as two of the author's cases show, osteochondritis dissecans is apt to provoke secondary arthritis obliterans, and when this is demonstrable by the x rays operative treatment should not be delayed even in the absence of symptoms. The procedure which the author inveighs against is to wait till some of the diseased bone has broken loose and then to be satisfied with the mere removal of the free body without eradicating its source. This course implies a second operation at a later date. At the first operation, therefore, removal of diseased bone should be as radical as possible.

360. The Prognosis for Dislocations of the Shoulder.
H. GUBLER (*Schweiz. med. Woch.*, September 28th and October 5th, 1922, pp. 960 and 985) points out that as dislocations of the shoulder represent from 51 to 54 per cent. of all dislocations, it is very important to be familiar with all dislocations under various conditions. He has collected the prognosis of the 252 cases occurring in 1920 and coming under the Swiss Accident Insurance administration. The value of this material, as compared with hospital cases, is

that it represents all shoulder dislocations—not merely such as have been admitted to hospital on account of their severity, and serious complications. The 252 cases were thus represented: subcoracoid 111, axillary 31, undiagnosed, or not recorded 41, posterior 1, complicated 40, and habitual dislocation 28. In 25 cases (10 per cent.) permanent disability was inflicted and compensation accorded. In 11 of these cases the dislocation was uncomplicated, in 12 it was complicated, and in 2 it was habitual. The average time taken in recovery was forty-eight days, and it was thirty-eight days for the uncomplicated cases. This period could, in the author's opinion, have been further considerably reduced had the practitioners in charge invariably adopted treatment by active and passive movements directly after the accident. As his survey of the literature shows, this procedure has never provoked a recurrence of the dislocation. And, as de Marbaix has shown, the period of invalidism may be reduced to an average of eighteen days by the immediate institution of mobilization. One of the patients in the author's material was a workman, aged 37, who resumed work as soon as the dislocation was reduced, and whose period of invalidism set up a record for brevity.

361. Operative Treatment of Ulcer of the Stomach and Duodenum.

E. HEDLUND (*Svenska Läkarsällskapets Handlingar*, September 30th, 1922, p. 167) has analysed the 485 operations performed at his hospital up to the end of 1920, and has come to the conclusion that the more radical the operation the more satisfactory and permanent are the results. He classifies his cases in two periods (1905-11 and 1912-20) and he notes that in the first period only 13 per cent. of the operations were resections of the pylorus, while in the second period this ratio had risen to 44 per cent. In the same periods the ratio of transverse resections had risen from 0 to 14 per cent., while the ratio of gastro-enterostomies had dwindled from 71 to 20 per cent. The operation mortality in the two periods was 4.5 and 6.5 per cent. respectively. This rise in the mortality was not, however, due to the increasing frequency of the more radical operations, but to comparatively accidental factors. The author's general impression that his most radical operations were the most successful was confirmed by an investigation of the after-histories of 455 patients, all but 22 of whom were traced. Complete recovery was achieved by primary resection of the pylorus in 73 per cent., and this ratio could be increased to 85 per cent. by adding the cases of almost complete or partial recovery. On the other hand, gastro-enterostomy was followed by complete recovery only in 30 per cent., and this ratio could be increased only to 54 per cent. by adding the cases of almost complete or partial recovery. The ratio of patients unimproved by primary resection of the pylorus was only 6.5 per cent., as compared with 17 per cent. of the patients treated by gastro-enterostomy. Only 2.5 per cent. of the patients treated by resection had to undergo a second operation, whereas 8 per cent. of the gastro-enterostomies required reoperation. Undoubtedly the risk of post-operative peptic ulcer is smaller after resection of the pylorus than after any of the other operations, and for this and other reasons the author is emphatically in favour of resection operations instead of gastro-enterostomies.

362. Colloidal Iodine in Gonorrhoea.

TANT (*Le Scalpel*, September 9th, 1922, p. 874) gives his experience in the treatment of gonorrhoea by colloidal iodine. Of the 167 cases treated 62 are eliminated because in 34 the treatment was not regularly carried out and in 28 the patients were still being treated. To abort the disease 2 c.cm. were injected three times a day. Only three cases presented themselves for abortive treatment, and of these one was cured in six days and two in seven days. Of the acute cases (28) the mean duration was twenty-three days and only six required treatment for more than a month. Of the chronic cases (74) the gonococci had completely disappeared in 53 after a mean treatment of thirty-seven days. The "morning drop" generally disappeared in three or four weeks. Of the total number (167) only one presented any complication, and that was an epididymitis in a man who had been treated for four days.

363. Post-operative Hernia of the Abdominal Wall.

O. NIELSEN (*Hospitalstudie*, July 5th, 1922, p. 65) has investigated the frequency with which a hernia followed laparotomy among 1,181 patients operated on in the period 1916-20. He personally sought out 495 patients who had not followed the injunction to present themselves at his hospital for examination a year after the operation. He thus obtained information as to the subsequent fate of 915 patients, and he classifies his material according as the operations were for diseases of the biliary passages or

stomach, or were situated in the right iliac fossa or in the pelvis. He further classifies his cases according as the operation wound was drained or closed at once, the latter class being again subdivided according as the operation wound became septic or not. The conclusion to which he comes is that there is little prospect of reducing the frequency of this complication by devising new lines of incision. Drainage and sepsis of the operation wound are the two chief factors promoting post-operative hernia, and doubtless if immediate closure of the wound were preferred to drainage more often than is usually the case the frequency of post-operative hernia would be reduced. But this is a less serious matter than the ill effects of inadequate drainage.

OBSTETRICS AND GYNAECOLOGY.

364. Treatment of Puerperal Septicaemia.

W. J. HUTCHISON and H. E. HARRIS (*New Zealand Med. Journ.*, August, 1922, p. 210), from an experience of 16 consecutive cases of puerperal septicaemia, consider that vaccine therapy, properly prepared and administered, is the most efficient remedy. Of 10 cases from October, 1915, to March, 1921, in which the usual treatment of douching, polyvalent antistreptococcal serum, stock vaccine, etc., was carried out, only one recovered, while of 6 cases since March, 1921, treated by autogenous vaccines prepared from the patient's blood, only one was fatal. Vaccines prepared from the uterine contents are unreliable. The method adopted which has given satisfactory results consists in an examination of the patient under an anaesthetic in the lithotomy position, taking a swab of the uterine contents for preparing a vaccine pending that from blood culture, curetting if necessary, and douching with 1 in 5,000 solution of potassium permanganate; 5 to 10 c.cm. of blood are then drawn from a superficial vein into a sterilized syringe, and this is added in varying amounts to three or four tubes of sterile broth, and a vaccine prepared and administered in 5-million doses every second day. The first dose generally produces marked improvement, and usually two or three doses are sufficient to bring the pulse and temperature down to normal. If the blood culture shows no growth in two or three days fresh cultures should be made and the intranterine douching should be continued until a vaccine is prepared. The organisms found in the blood are not always similar to those found in the uterus, and in one case, while the first blood cultures showed no growth, the uterine swab gave a pure culture of streptococcus, and, though the vaccine therefrom had no effect, excellent results followed the administration of a vaccine from a second blood culture, which gave a pure growth of a haemolytic streptococcus. Failures in the past have probably been due to improper dosage and at too long intervals, and since vaccine therapy on the above lines has been carried out every case of puerperal septicaemia yielding a growth of organisms from blood culture has recovered. Pleuritic pain with subsequent effusion occurred in three of the six reported cases, though in only one was recovery delayed thereby.

365. Hyperplasia and Myomata.

HEITZ (*Gynéc. et Obstét.*, 1922, vi, 3, p. 208) confirms the frequency of the association in females of high blood pressure with the presence of uterine myomata, as first pointed out by Vaguez. Among 208 women having high blood pressure he found that no fewer than 45 had or had been surgically treated for myoma; increased arterial tension was specially common in those in whom haemorrhage had been checked by hysterectomy or x-ray treatment. These findings are not in accord with the views of those who regard high blood pressure as a consequence of renal changes. The practical lessons to be learnt are that too radical suppression of haemorrhages which may have some beneficial effect is not without danger, radiotherapy in carefully selected cases presenting advantages as compared with hysterectomy; and that it is important that patients after treatment for myomata should be kept under continued medical supervision, especially as regards the circulatory system.

366. Puerperal Thrombosis and Embolism.

P. HÄGGSTRÖM (*Uppsala Läkareförenings Förhandlingar*, September 11th, 1922, p. 305) has investigated the frequency with which thrombosis and embolism occurred among 11,475 maternity cases at the University Hospital in Uppsala. There were 149 cases of thrombosis, 13 of which led to embolism, which proved fatal in 6 cases. Collecting the figures of fifteen other writers, the author has obtained a total of 140,752 maternity cases, among which there were 882 cases of thrombosis (0.6 per cent.) and 80 of embolism (0.06 per cent.). The calculation is made that, as 125,000 to 135,000

children are born yearly in Sweden, approximately 1,000 women suffer every year from puerperal thrombosis, which leads in about every tenth case to pulmonary embolism. For every 2,000 births there is one death from pulmonary embolism, and it is probable that in Sweden alone 60 to 70 women die every year from this condition. Puerperal thrombosis increases with age; in the author's material its incidence was only 0.6 per cent. among women under 20, whereas among women over 40 it was as high as 2.7 per cent. Among primiparae it was only 0.9 per cent., as compared with 1.6 per cent. among multiparae. A point on which the author lays stress is the importance of the premortuary signs given by the pulse and temperature. Among the 132 cases of thrombosis in which a record of the pulse was kept there were as many as 97 in which the pulse rate ranged from 90 to 140 before the thrombosis was detected; in 95 cases there was also a premortuary rise of temperature. The pulse and temperature are therefore a useful guide, and when raised they should lead to a search for signs of thrombosis. The author's statistics also show that the incidence of thrombosis is somewhat higher among patients who have been examined internally in connexion with labour, or have had a ruptured perineum sutured, than among women who have not had to submit to either of these procedures.

367. Simultaneous Uterine and Ectopic Gestation.

A. SIPPEL (*Deut. med. Woch.*, September 8th, 1922, p. 1202) records a case to which he can find only two parallels in the literature. A multipara, aged 39, was operated on for tubal abortion seven weeks after her last menstruation. At the operation he was surprised to find a uterine pregnancy of the same date as the pregnancy of the right tube. This was removed with great care, and the patient went to term, giving birth to a well-developed child on June 1st, 1920. She menstruated regularly till July 17th, 1921. On August 7th, 1921, she was operated on for a tubal abortion on the left side, pregnancy having evidently lasted seven weeks. Uneventful recovery followed. In connexion with this case the author discusses the advisability of operating on both sides on the occasion of a ruptured extrauterine pregnancy in order to prevent a recurrence of this condition on the other side. It has been calculated that about 5 per cent. of all cases of ectopic gestation sooner or later involve both sides, but, as there may be normal intrauterine pregnancies in the interval, ligature of both tubes may not always be justifiable.

PATHOLOGY.

368. Immune Serum in Yellow Fever.

HIDEYO NOGUCHI (*Journ. Exper. Med.*, September, 1922, p. 357) has studied the duration of the protective effect of anti-icteroides immune serum after subcutaneous inoculation into animals. It had been found that when non-immune persons contracted yellow fever notwithstanding vaccination, the onset occurred soon after vaccination, and since the incubation period in yellow fever is six days it seemed that infection must have taken place in some instances during the period while protection was developing. On the other hand, immune serum protects at once against experimental *Leptospira icteroides* infection, and it might be possible to provide immediate protection by means of anti-icteroides serum. It was found with guinea-pigs that complete protection enduring five days was provided by very small quantities of serum, but that after five days the immune substance rapidly diminished, and to keep the animal protected for as long as ten days it was necessary to give a hundred times as much protective serum. This sudden disappearance of the immune substance after about ten days may be connected with the precipitin formation for the heterologous anti-icteroides horse serum. But since the titre of the immune serum suffers reduction when kept at 37° C. *in vitro* a similar reduction would certainly be expected in the blood of a foreign species. Noguchi's results suggest that for a man weighing 80 kilos 0.16 c.c.m. of serum would theoretically be sufficient to protect for at least five days and 16 c.c.m. for ten days. This temporary protection would be a valuable antecedent to that furnished by vaccination, since the final effect of the latter cannot be expected until at least nine or ten days have passed.

369. Basophilic Inclusions in Polymorphonuclear Leucocytes.

J. SABRAZÈS (*Gaz. hebdom. des Sci. méd. de Bordeaux*, October 1st, 1922, p. 470) finds that it is possible by certain staining reactions to distinguish between two different kinds of basophilic staining substances which occur in the cytoplasm of polymorphonuclear leucocytes. The one kind is encountered more

or less often in scarlet fever and in the majority of the infectious diseases, and is stained blue by May-Giemsa; the other, which is altogether more rare, results from nuclear disintegration, and is coloured red by this dye. For further differentiation Pappenheim's mixture of carbol-fuchsin, polychrome blue, and methyl green may be used; this stains chromatic green, spongioplasm blue, and the basophile paraplasm red. With this reagent the basophilic inclusions of the first type appear blue, and may therefore be regarded as the remnants of the spongioplasm of the original myeloblasts. Leucocytes containing such inclusions have attained nuclear but not cytoplasmic maturity. Their cell substance still retains tiny areas which have escaped the oxyphilic change of the paraplasm and its granular infiltration. A simpler method of distinguishing these inclusions from fragments of nuclear material is to examine a dried blood film under a cover-slip after treatment with carbol-toluidine; the former are stained a greyish-blue colour, while the latter take on a beautiful red wine shade.

370. Histopathology of Filter-passing Virus of Influenza.

G. BAEHR and L. LOEWE (*Arch. Intern. Méd.*, September, 1922, p. 307) describe the pulmonary lesions produced in rabbits by the intratracheal inoculation of Berkeley filtrates of naso-pharyngeal washings from early cases of influenza, which are as follows: (1) Congestion, oedema, and small haemorrhages in the mucous membrane of the trachea and bronchi. (2) Presence of a profuse, slightly blood-tinged, frothy, serous fluid in the lumen of the bronchi. (3) Diffuse patchy distribution of red, jelly-like lesions throughout the lungs. (4) Intense congestion of a large part of the intervening lung parenchyma and acute emphysematous overdistension of alveoli. (5) Widespread exudation of serum and extravasation of red blood cells from the vessels, filling interstitial tissues and groups of alveolar air spaces. (6) Aplastic, structureless character of the exudate. (7) Aneurysmal dilatation of short stretches of capillaries and arterioles, and sometimes closure of the lumen of these vessels at these sites by blood platelet thrombi. (8) Tendency to early secondary invasion with pyogenic organisms, which then induce a rapid purulent infiltration, thereby completely obliterating the primary and specific picture of the disease. Similar lesions were produced by the intratracheal inoculation of cultures of the filtrable punctiform bodies cultivated from naso-pharyngeal washings in early influenza. These specific pathological characteristics have all been observed in human influenza by pathologists who have had the opportunity to study the lungs of patients with fulminating disease who died within the first few days of their illness and before secondary infection had occurred. They can best be explained on the supposition that the virus of this disease possesses a remarkable affinity for the vascular endothelium. The virus gains access by the respiratory passages, and is rapidly absorbed through the mucous membrane of the trachea, bronchi, and bronchioles, when, as the result of its peculiar endotheliotoxic property, it rapidly causes a profuse outpouring of serum and red blood cells in patchy areas throughout the lungs. The complete loss of tone in many capillary loops and the early occlusion of many capillaries and minute arterioles by blood platelet thrombi are further evidence of this vascular damage.

371. A New Medium for the Gonococcus.

S. COSTA and L. BOYER (*C. R. Soc. Biologie*, July-September, 1922, p. 856) claim to have secured good results in the isolation and preservation of the gonococcus from a medium whose chief characteristic is the replacement of the usual non-coagulated protein by powdered gum, obtained from the exudation of the *Astragalus gummiifer* and trees of neighbouring species. In preparation a peptone-beef bouillon is made up, altered, and made slightly attractive to litmus (exact pH not given); 1 per cent. of gum is then added in small quantities at a time, and the fluid agitated till a homogeneous mixture is obtained; 3 per cent. agar is used for rendering the medium solid, and the usual filtration and sterilization performed. The finished product is almost as transparent as ordinary nutrient agar, but the surface is moist, more viscous, and more sticky. The gonococcus will live on it for eight days. For keeping the organism, once it is isolated, they find that a semi-liquid medium, prepared in the same way but containing only 0.3 per cent. agar, is more serviceable; on this the gonococcus will remain alive for a month or longer. That the value of the gum does not depend on the starch it contains they have shown by adding sufficient malt to the medium to ferment all the starch; the subsequent growth obtained is not diminished in any way. They have therefore come to the conclusion that the action of the gum is probably more of a physical than a chemical nature, serving to produce a peculiar degree of humidity and viscosity which is favourable to the growth of the gonococcus.

NINETIETH ANNUAL MEETING
OF THE

British Medical Association.

Held at Glasgow, July, 1922.

PROCEEDINGS OF SECTIONS.

SECTION OF PATHOLOGY (HUMAN AND
COMPARATIVE).

Professor ROBERT MUIR, M.D., F.R.C.P. Edin., F.R.S.,
President.

DISCUSSION ON
ANIMAL AND VEGETABLE PATHOLOGY IN
RELATION TO HUMAN DISEASE.

OPENING PAPERS.

I.—ANIMAL PATHOLOGY IN RELATION TO HUMAN
DISEASE.

FREDERICK HORDAY, O.M.G., F.R.C.V.S., F.R.S.E.,
Honorary Veterinary Surgeon to H.M. the King; formerly Professor in
the Royal Veterinary College, London.

THE study of animal and vegetable pathology has many points in common with that of the study of human disease, and will well repay a much greater research in the future than has been made in the past.

Members of the medical and veterinary professions have much in common, and to collaborate more closely and interchange their ideas cannot help but be of mutual benefit, not only to themselves but to the world in general, as the day of the "watertight compartment" system of opposing the ravage of disease is past. By progressing hand in hand much interlocking of ideas and side-tracking can be avoided and a more rapid advance gained against the common foe.

The vegetable aspect of the question is in the able hands of Professor Lang, F.R.S., and in the time at my disposal I shall endeavour to draw your attention to some of the salient reasons which concern animal pathology in relation to human disease.

That there are a number of diseases communicable from animals to man is well known, but the important part played by the trained veterinarian in preventing this communication has not yet been sufficiently appreciated, and in certain of these diseases the worker on the animal side must, of necessity, occupy the front trench, in order effectively to protect his medical colleagues and their human patients.

We have at the present time in Great Britain at least the following, which are indisputably communicable: glanders, rabies, anthrax, tuberculosis, foot-and-mouth disease, cowpox, mange of all animals (horses, cattle, dogs, and cats), ringworm (especially of the horse, calf, cat, and mouse), and certain forms of seborrhoea (such as blacksmiths contract from handling horses with greasy legs). The *Bacillus abortus* of Bang is also under suspicion as a source of contagion from cattle, and I think that the great prevalence of pyorrhoea in pet dogs (which are kissed by their fair owners and allowed to lick their lips and hands) should be regarded as a possible factor in the spread of that disease in human beings.

Others produced by parasites require an animal host in order to make their respective life cycles complete before they can become pathogenic to man, such, for example, being the echinococcus, the *Cysticercus bovis* (the larval stage of the *Taenia saginata* of man) and *Cysticercus cellulosae* (the larval stage of *Taenia solium*), the parasites of mearly beef and mearly pork respectively; and the *Trichina spiralis* of the muscles of the pig, which give rise to trichinosis in man in countries where ham is largely eaten smoked and not necessarily cooked.

Then, in addition to those which are intercommunicable, we have in animals many diseases which are analogous to those in man—analogue in many ways in symptomatology, in the situations of the body which are attacked, in the ravages set up in the various body organs and in other ways, the knowledge of which sets one thinking, and often deters one from making grave errors of diagnosis and judgement.

Take, for example, the old-time instance of the man with the cirrhotic liver. There was a time when excessive indulgence in alcohol was almost always blamed for this, and the term given, "gin-drinkers' liver," was a byword. Animals, and not alcohol, and yet cirrhosis of the liver is one of the commonest things observed when making post-mortem examinations of old animals.

The study of cancer is equally interesting in animals as in man, probably almost more so, and the situations on which this disease occurs in our respective classes of patients are well worth serious thought when considering the irritation, and other, theories.

The knowledge that certain species of animals are refractory (or even completely immune) to certain diseases is of enormous value to the student of disease problems, and this fact requires a satisfactory explanation, if only it can be discovered. The immunity of the ox tribe to glanders is the best illustration of a disease of this kind.

Why should the ox be immune to glanders, when the horse, ass, mule, certain carnivora, and man, fall easy victims to it? There must be a valid reason, and if only that knowledge could be attained, and put into practical shape for purposes of conferring immunity on those susceptible, the fight against glanders would have scored a point—a great point, too—on the side of progress. Then again, one must not forget the danger of the animal as a carrier of disease, so that to the scientific worker a knowledge of the habits of the animal in health is as useful and necessary as a knowledge of the symptoms when in a state of disease.

Too time is not long enough to take each disease in full detail, as to each one might allot a whole day, and then not exhaust all the comparative aspect, so that it is my intention briefly to bring forward for your consideration the most salient points which affect man and the lower animals mutually, and particularly emphasize in this category the value of a mutual collaboration between the medical and veterinary professions.

Let me read you a brief paragraph I cut out of a morning paper only so recently as the 6th of last month. A Reuter telegram which was sent from Helsingfors, and came to London via Paris, is as follows:

"The Soviet Red Gazette announces that the Bolshevik authorities in one of the famine districts, 'for humanitarian and sanitary reasons,' have shot 117 children afflicted with glanders which developed after eating the flesh of horses suffering from that complaint."

It makes one meditate, safe within this England of ours, what can occur when the laws of preventive comparative medicine are disregarded, and is a striking instance of the value of the trained veterinarian to his medical confrère and the general public.

Glanders and rabies, two of the most horrible diseases which can affect man or beast, show what can be done by organized collaboration of the two professions. Each is primarily a disease of animals, and only comes to man from them.

Let the veterinary scientist eradicate glanders from his patients of the horse tribe, and rabies from the canine race, and neither of these diseases will appear in man; and I am happy to say that there is every reasonable hope that by the end of this year this will have been achieved in regard to Great Britain. The credit for this important result, which is of equal importance to man and animals, must be given entirely to those to whom it is due, the veterinary advisers (with Sir Stewart Stockman and Sir John McFadyean at their head) of the Ministry of Agriculture; and so long as we maintain a rigid system of mallein testing and quarantine under expert veterinary supervision on all animals of the horse tribe before they are allowed to enter the country, there will be no danger of the reintroduction of glanders to Great Britain.

Glanders.

I can remember the time when London was so full of glanders that every stable groom, and particularly those in cab and omnibus stables, knew the meaning of the word "glanders" as well as he knew the hour of his midday meal.

In 1901 (only twenty years ago), some 2,370 horses were destroyed for glanders in Great Britain (1,828 from London alone); whereas the statistics of the Ministry of Agriculture show that for this year, up to the present date, no case has been reported.

The discovery of mallein, and the mallein test, placed in our hands an infallible method for the detection of glanders, and by its means the disease can within a very short space of time be, with certainty, eradicated.

By its aid, applied by the officers of the Royal Army Veterinary Corps, glanders was completely kept under control amongst the hundreds of thousands of horses and mules in the British army during the recent war; and afterwards some 150,000 were sold to the public with perfect safety; and I believe I am right in saying that, in the British army, no case in man was reported during the whole of the war.

Twice have I been present officially in civilian life at the *post-mortem* examination of men who had died of glanders, and in neither case was the disease suspected by the medical attendant until just before death, one patient being treated for about ten months for chronic rheumatism and the other for chronic pleurisy.

The infection is usually transmitted to man from a glandered horse, ass, or mule, by discharge from the nose, from a farcy bud, or by contact of an abraded surface with a sponge or brush (stable intensil) which has become contaminated with some of the infectious discharge from a horse or mule. The men most commonly infected are those whose life brings them in contact with horses or with the preparation of glanders cultures, and records in medical journals show the hopelessness of treatment when once the disease has gained a foothold.

I believe I am correct in saying that there is only one man alive in Great Britain at the present time who had been indubitably infected with glanders and completely recovered. I refer to Professor Gaiger, the energetic Principal of the Glasgow Veterinary College, who has published a full description of his own case in the *Journal of Comparative Pathology and Therapeutics* (1913 and 1916). It is a most fascinating account of a plucky fight against a loathsome and terrible disease, and is of great scientific interest.

It is appropriate that Professor Gaiger should be with us at this meeting to-day, and I am sure that I am expressing the wishes of all of us who are present when I say that we all, medical and veterinary alike, congratulate him and his medical advisers on the successful issue to the gallant fight that was made for his life.

Rabies.

The energetic watchfulness of the veterinary officials of the Ministry of Agriculture has kept Great Britain free from rabies for nearly twenty years, and until some thoughtless person committed the stupid and criminal offence of surreptitiously smuggling a dog (which happened to be infected and in the incubative stage) into the country, the much dreaded disease existed in this country only in name.

The first case was reported in the district of Plymouth about May, 1918, and during 1919 alone some 179 persons were bitten by animals in the scheduled areas, 46 of them by animals proved to be rabid. Prompt measures were taken, and treatment was arranged by the medical department of the Ministry of Health, and it is a triumphant tribute to the memory of Pasteur that there have been no deaths in England from hydrophobia. Under the present laws the head and neck of a suspected dog are sent to the Veterinary Laboratory of the Ministry of Agriculture, together with as much history as can be collected by the veterinary inspector to whom the case has been reported. The Negri bodies are searched for and inoculation made if necessary, with the result that in 96 per cent. of cases a decision can be given

within a few hours, thus saving those who have been bitten much painful suspense and anxiety; and, what is more, enabling the medical officer, if necessary, to advise and immediately commence antirabic treatment.

All Continental countries, with the exception of Norway, Sweden, and Denmark, are infected, and although mainly seen in the dog, rabies is also met with in the horse, cow, sheep, cat, fox, wolf, and even the fowl.

In some of these veterinary patients rabies produces a train of symptoms which are rather curious, and which to the layman may not give rise to any suspicion of the disease, and thus perhaps lead to disaster.

Everyone knows something about the suspicious signs in the dog, although the classical symptoms are by no means constant. The change of manner, desire to hide in dark places, great excitability, restlessness, snapping at imaginary objects, attempts to swallow, the futile attempts to drink water, and the final rage in the violent forms, or the typically dropped jaw in the paralytic form, are all characteristic of the rabid dog. It is strange, too, what long distances dogs will wander in their unconscious frenzy, and it is for this reason that large areas have to be placed under restriction. The bark becomes changed and the peculiar howl of a rabid dog, once heard, can never be forgotten. Paralysis of the hind quarters and complete exhaustion finally close the scene if the disease is allowed to terminate the poor brute's existence.

A rabid cat is even more to be feared than a rabid dog, as it will attack either man or animal in a most reckless fashion; the disease terminates in death preceded by a stage of paralysis of the hind quarters. In the horse and ox one particular symptom which has been frequently observed is a tendency to attempt to bite or rub the scar at the site of infection, whilst in the sheep sexual excitement has frequently been noted.

Until the muzzling order has been finally withdrawn from every district it is necessary for both medical and veterinary practitioners to be on the alert for rabies, but there is every reason to hope that before the end of this year this disease, like glanders, will be relegated to its place with those which are only memories and no longer realities.

Here again the veterinarian can say that he is of signal service to his medical colleague.

Anthrax.

Anthrax has been very much in evidence, both as regards man and animals, during the past few years, and it is time that very much sterner preventive measures were taken against it. As the editor of a professional journal I get cuttings from press agencies all over the country, and it is rare for a week to pass without receiving evidence of its appearance in either man or beast. When it is of sufficient importance for the public press to notice it constantly one may reasonably surmise that it has become fairly prevalent.

It is a scheduled disease, and Government statistics prove its prevalence in man, particularly amongst those who deal with skin, hides, wool, and hair from abroad, and those who make, or assist at, *post-mortem* examinations of animals dead of it.

The veterinary practitioner sees the disease most commonly in cattle, although it may be met with in the horse, sheep, pig, and even the dog; the latter animal is, however, less susceptible than the others.

Bone manure, foreign cake, and other feeding stuffs, obtained from countries where anthrax is rife and improperly controlled, are blamed largely for its appearance amongst stock. It is a

FIG. 1.—Intradermo-papular reaction to mallein. (From the clinical article in the *Veterinary Journal*, August, 1920, by Captain Howard B. Collet, B.V.Sc., M.R.C.V.S.)

troublesome disease and difficult to control, but the precautions of the Ministry of Agriculture have reduced the number of outbreaks very considerably; and if only the disinfection of imported things such as hides, wool, and hair, and even the much abused Japanese shaving brush, can be effectually controlled on entry into the country we shall hear of fewer cases in man. The same may be said in regard to the supply of cotton and other cakes imported into Great Britain as a food for cattle.

It is practically always through animals or animal products that anthrax reaches man, so that to stamp it out of the lower animals would mean its eradication from man—a further proof of the necessity for close combination between the veterinary and the human medical professions, and the importance of the study of animal pathology in relation to human disease.

Several communications to be read before the meeting to-day bear on the subject of the intercommunicability of this disease from animals to man, and its seriousness when once contracted.

Selavov's serum, the sheet anchor in the human treatment, is unreliable for the animal, and both in horses and cattle this disease still holds its own as one of the most rapidly fatal, for the patients of the veterinarian, of all the microbial diseases.

Tuberculosis.

If there is one disease more than another to which attention is to be drawn as an instance of the importance of animal pathology in relation to human disease, it is tuberculosis. To medical men and veterinarians alike it is one of the most important and devastating diseases of the day, and when one reads statements that no less than 85 per cent. of the cases of tuberculosis of the glands of the neck occurring in children are of bovine origin, that over 10,000 children die annually from drinking tuberculous milk, and that we have fully a million tuberculous cattle in Great Britain, it makes one shudder and wonder what our sanitary advisers and legislators are doing in regard to tackling the question from the animal stand point.

One scarcely ever picks up a daily paper without reading some statement or other about tuberculous milk, and I cannot understand why the Cattle Tuberculosis Order, which was really making headway in 1914, and was temporarily suspended during the war, has not been re-established.

The report of the Medical Officer of Health for the City of London (Dr. W. J. Howarth) for 1921 states that out of 50 consecutive samples of milk purchased in the City no less than one in four proved to be tuberculous; and Dr. Bigger, at the last meeting of the Statistical and Social Society of Ireland, asserted that 6 per cent. of all deaths from tuberculosis was due to drinking tuberculous milk.

Does it not seem astonishing that such a state of affairs can exist in Great Britain, the richest and most sanitary country in the world? Yet we do not move, although it costs us 10,000 human deaths annually, and the loss of many hundreds of thousands of pounds to the agricultural and dairying communities.

Surely it is time a move was made to enforce that milk, when sold, should be clean and free from tubercle, and, if it is not asking too much at this, my first appearance before you, I would like a resolution to go up from this meeting in similar terms to that which was unanimously passed at the combined meeting of the Royal Society of Medicine and the Central Veterinary Medical Society, on the proposition of Sir John McFadyen, in March last, namely:

"That the prevalence of tuberculosis in cattle in this country continues to be a serious menace to the health of human beings, and that to counteract this danger, the re-introduction of the Tuberculosis Order, which was suspended in 1914."

Given a free hand, we of the veterinary profession could stamp out tuberculosis of cattle in the same way as we have stamped out glanders and rabies. It would take time and would cost money, but the saving of the suffering and misery entailed by the loss of 10,000 human lives annually would more than counterbalance that, and surely should weigh down the right-side scalepan. Money ought not to count where human life is at stake. Having done our part, it would then rest with us to see that this bovine scourge never again got the upper hand, and was relegated to the same position which is now held by glanders and rabies. By doing so we should have again proved the value of having worked together, as opposed to the plan of separate and watertight compartments.

At the present moment a method of immunization of calves, introduced by Dr. Nathan Raw, is on trial, but it is too early yet to say anything about its results. Should it prove successful, it will be one of the greatest boons ever conferred upon the agriculturist, and, through agriculture, to mankind, for it will materially help to abolish this dire disease from this country.

Foot-and-Mouth Disease.

Although mainly a disease of cattle, sheep, and pigs, foot-and-

mouth disease is of importance because of the risk of the milk for mankind, especially for children. For the moment it has gained a footing in Great Britain, and has cost the taxpayer already over a million pounds. A few instances have been reported of contagion to man, but in reality, owing to the strict quarantine and stamping-out methods of the officials of the Ministry of Agriculture, the disease has not had much opportunity to spread in this direction. Beyond, therefore, alluding to it in passing, and making the statement that it is one of the most insidiously contagious diseases of cattle with which we have to deal, I will not dwell upon it now. Some indication as to the extent to which it will spread may be gathered from the statement that in 1892 in Germany no fewer than 1,504,299 cattle, 2,193,157 sheep, 17,782 goats, and 438,262 pigs were affected in one year's outbreak alone.

Cow-pox.

This disease, too, I propose to pass over with a mere allusion, as it has, since the time of Dr. Jenner, received such widespread publicity that its position is definite, and everyone—whether medical man, veterinarian, or agricultural herdsman, knows full well its importance in animal pathology in relation to human disease. It is highly infective from cattle to man, and although its course in man is tolerably benign, yet it is one of those little things which we would rather be without.

Mange.

The horse, cow, camel, pig, dog, and cat each has its special varieties of parasite, and it only needs a certain length of time in contact with the skin of man for the acarid to change his residence.

Three varieties of parasite are found on the horse—a sarcoptid, a psoroptid, and a symbiote, the two former being those which most commonly transfer themselves to man.

Grooming a mangy horse is risky, and riding one is almost certain to transmit the ailment. Knacker men are frequently

FIG. 2.—Typical eye (intra-dermal) and neck (hypo-dermic) reactions on a glandered horse. (Captain Hewer's clinical article, *Veterinary Journal*, vol. 27.)

infected when employed in skinning mangy horses; and a recent case reported in the *Lancet* by Mr. A. S. Macdonald, B.Sc., M.R.C.V.S., proves that the veterinary student is by no means immune. The circumstances were a little peculiar, and worth relating:

A class of veterinary students were engaged in performing post-mortem operations on a horse. The horse had generalized sarcoptic mange, and was very badly affected. It was destroyed one Saturday morning at 10 o'clock, and thereafter was left lying upon a concrete floor while the students in question palpated, dissected, and operated upon the carcass for a period of time which varied with the individual from two to five hours. Of the students who had any contact with the carcass in question, approximately 53 per cent. became infected. On the other hand, the non-infected individuals were either those who were engaged upon the head and neck (which parts had been cured by the previous treatment) or those who had been little more than onlookers, in that they had been engaged in swabbing incisions, etc., to assist the actual operators. In short, of those students whose hands and clothing came into direct and prolonged contact with the infected carcass 100 per cent. complained of subsequent symptoms.

The most constant symptoms common to every case were:

(a) Itch of a most pronounced and continuous nature, accentuated by surface warmth, induced by exercise, by lying in bed, and by friction in the process of innervation of the affected areas.

(b) A papular eruption. This was present in all the affected cases at the site of contact with the carcass—i.e., forearms, ankles, and calves of the legs. The hands in most cases, though not in all, escaped infection, no doubt owing to washing with carbolic soap immediately after, or in some cases during, the work on the dead subject. In some cases the forearms erupted while the ankles were affected, or vice versa. Lesions on the shoulders, upper arms, trunk, and thighs occurring in some of the students were in all cases secondary, there being no direct track of infection on the skin. The papules were the size of a large pin's head, of a fiery-red colour, and were slightly elevated above the surface of the surrounding skin. They seemed to correspond to hair follicles, and the crops were luxurious. It is perhaps significant that in one the interdigital spaces were the seat of the infection; here also the papules were more circumscribed, more elevated, and slightly pointed.

Treatment was troublesome, consisting mainly of hot baths and the after application of sulphur preparations, but eventually all made a complete recovery.

In Great Britain mange in the horse is a notifiable disease, and must be reported to the authorities, but mange in the dog is not.

That mange in the dog and cat is transmissible to man does not seem to be so generally known in the medical profession as it should be, and some time ago Dr. Whitfield and myself published the histories of some seventeen cases, in which I had confirmed the existence in the human subjects, and I in the dog.

In a canine *clientèle* one frequently gets a person with an itchy dog who complains of an irritable skin, and in a very high proportion of cases, if the dog has mange, the owner will have contracted it. Small vesicles are produced, scattered over the surface, and not in grouped lesions. The intense irritation leads to scratching and the consequent decapitation of the little vesicles, and their original site becomes covered with a scrous or a blood scab. If left untreated, the canine sarcopt will live on the human subject for about six weeks, but, if recognized and treated, I understand that it is easily got rid of. Several communications upon this subject will be presented to you by others interested in the comparative pathology side of the question.

Ringworm.

All the ringworms of animals are contagious to man. Every cowman knows of the risk he runs when dressing calves, or cattle, suffering from this complaint, and the ringworm of the horse is also contagious. The man who gets infected with either does so with his eyes open; but in the coat of the domesticated cat there lurks an unexpected danger which might not occur to one to suspect, did one not know. The cat's hair can be a carrier of ringworm spores without necessarily becoming infected to a sufficient extent for an owner to see it. In fact, it may escape the attention of the medical attendant and veterinary attendant alike for a considerable time; to fix this upon your attention I shall ask you to take note of the report of a case of transmission of ringworm from a cat to some children, which has been sent to-day by Mr. E. Livesey, M.R.C.V.S., in detail:

Briefly, the facts were that Mr. Livesey was asked to examine a young cat, in regard to the presence or absence of skin disease. He failed to find anything, but within three weeks developed tinea

circinala on his left wrist, several other places following later. His wife, too, developed lesions. The owners of the cat developed it, as also five other persons in the house of a friend to whom it was given as a present. Further microscopical examination of the hair of the coat behind the ears revealed tinea spores, and the source of the infection was thus explained. In all, 15 people were affected.

Measles, Trichinosis, etc.

To the diseases found in meat I propose to do no more than allude, as they in themselves would form a separate paper of great importance. Suffice it to say that they play their part in the category covered by the title of the paper, in that they come under "Animal pathology in relation to human disease." Their presence furnishes a plea for proper and efficient meat inspection, the general neglect of which in England is deplorable.

It is entirely owing to the fact that we cook our food well that we enjoy our freedom from diseases in which a portion of the life history must be spent in an animal and part in man; a further tribute to the necessity for the study of comparative animal pathology.

Conclusion.

In conclusion, I desire to congratulate those of the Committee who selected as the title for the discussion "Animal and vegetable pathology in relation to human disease," for its part is an important one, and there are numbers of diseases which are intercommunicable and analogous. It behoves us to work together, to exchange ideas, and to work in unison, and by doing so we shall hasten forward the good work which is being done daily in the combat against disease.

Note.—A number of case reports and actual instances of the above diseases being communicated from animals to man were read by the ex-*arist* at intervals during his paper, the names of the medical and veterinary authors being given in each case. Space does not permit of these being given in detail.

II.—SOME ASPECTS OF VEGETABLE PATHOLOGY IN RELATION TO HUMAN DISEASE.

BY

WILLIAM H. LANG, M.B., D.Sc., F.R.S.,

Baker Professor of Cryptogamic Botany, University of Manchester.

DIRECT comparisons between the normal development and construction of plants and animals have often proved more misleading than helpful, and it is even more necessary to be on guard against false analogies when the comparison is extended to pathological processes. The common features of all living things justifies the attempt, but it is well to maintain a critical rather than an optimistic attitude.

Evolutionary history shows that the connexion between plants and animals lay very far back, and is particularly indirect for the higher animals and the higher plants. Pathological reactions and processes have a similarly long history behind them, though we can hardly hope to get more than occasional records of them from the fossils. If we could compare the reactions, for instance, to wounding, in the earliest vertebrate animals and the earliest land plants we should doubtless find them as dissimilar in essentials as those of a man and a flowering plant to-day.

Some ancient plants recently found in the Old Red Sandstone of Scotland afford the earliest examples of pathological reactions of the tissues of plants that I know. These plants had, like other land plants, an epidermis with minute openings or stomata through which gaseous interchanges between the air and the internal atmosphere in the inter-cellular spaces took place. Noxious gases, perhaps the result of volcanic activity in the neighbourhood, appear to have sometimes entered the stomata, stimulating the cells around and underneath to enlarge and divide. The interest of the small projections of tissue thus produced lies in their remarkable similarity to the tumescences formed in some living plants when exposed to irritating vapours. The resemblances of the pathological reactions of these Devonian plants and those of the present day do not stop here. When the unknown cause had led to the necrosis of a portion of the tissues of the stem, the adjoining living cells reacted by enlargement and repeated division to the presence of the necrosed mass or the wound left by its decay and disappearance. The result in some cases is as beautiful an example of wound-callus, progressing towards the obliteration of the cavity and the healing of the wound, as can be obtained from living plants. The perfection of the preservation of this, the most ancient wound reaction that is known, is of interest for its own sake, and will serve as a starting point for some general

considerations on reactions of vegetable tissues to irritants and parasites.

Even from this example it will be obvious that a general correspondence can be traced between the healing of a wound in the plant and animal body. If, however, we were tempted to make more specific comparisons—for instance, between the processes of the wound-callus and the projections of granulation tissue in an animal wound—we should probably get astray and pass from scientific study into regions of fancy.

The same general conceptions arise in the study of diseases of plants and animals, and the same names, such as wound reactions, parasitic diseases, and tumours, are naturally used. The interest of comparison in all these cases has long been recognized by human pathologists, though it can hardly be said to have been actually useful.

Of late years very direct comparisons have been made between a remarkable disease of plants known as "crown gall" and malignant tumours in man and animals. It will afford the necessary limitation to the scope of my remarks if they are made to bear on the consideration of this disease and of these comparisons. I venture to do this since I have had the advantage of being in close touch with a study of crown gall which Dr. Wilfrid Robinson and Mr. H. Walkden have been making in my laboratory. Without anticipating their results, which will shortly be published, this will enable me to present some of the problems suggested by the published accounts of this disease in a form that may be of use in this discussion.

The tumour-like growths of crown gall have long been known, especially in relation to wounds made in cultivated plants from horticultural operations such as grafting. The disease was proved to be transmissible from one plant to another, and was later shown by Smith and Townsend to depend on a bacterium which they successfully isolated and named *Bacterium tumefaciens*. The causal organism having thus been obtained in pure culture, the experimental production of the disease has been extensively carried out, especially by Erwin Smith. We owe much of our knowledge of crown gall to his papers, which contain a wealth of illustration by excellent photographs of the varied effects of the introduction of *Bacterium tumefaciens* into a number of different plants.

Bacterium tumefaciens is a rod-shaped bacillus with rounded ends, 1.2 to 1.5 μ long by 0.5 to 0.6 μ broad, and motile by means of one, or occasionally two or three, polar flagella. Its cultural reactions have been fully studied by Smith and, as independently isolated in this country, by Walkden. Its regular occurrence in relation to the crown-gall tumours has been proved bacteriologically by obtaining from them pure cultures of the organism which can again cause the disease.

The main features of the growths caused by this bacterium may be briefly stated. There is no evidence that infection occurs except by a wound, though a needle-prick is sufficient. The galls have been obtained on roots, stems, and leaves of many plants, attaining the largest size when the inoculation affects immature tissues or the cambium of stems with secondary growth. Especially large tumours form on parts with very active and anomalous secondary thickening, such as the root of the sugar beet. What have been distinguished by Smith as secondary tumours appear in some cases at a distance from the main tumour. When the inoculation is made into apical or axillary buds the further growth of these is profoundly disturbed and irregular growths bearing more or less altered organs (leaves, shoots, flowers) result. Definite organs of the plant may also appear on tumours apart from pre-existing rudiments. Thus roots develop in the condition known as "hairy root," and shoots when inoculations have been made on the cut surface of a young internode, into the internode of a stem, or into the midribs of a young leaf.

The tissues of the gall or tumour, resulting from the stimulation of unknown nature exerted by *Bacterium tumefaciens* on the more or less immature part of the host plant, show an abundant irregular multiplication of cells. Some of the resulting meristematic cells undergo differentiation into mature tissue elements, especially into those of an irregularly arranged wood. Others may form the starting point for the adventitiously developed organs (roots, shoots) mentioned above. The published figures show that the effect may extend back some distance from the inoculated surface in the vascular bundles. Smith holds that there is an actual infiltration of the tumour cells between the normal cells of the tissues around, and explains in this way the origin of the

secondary tumours connected by tumour strands with the main tumour.

On the ground of such facts as have now been summarized Smith makes detailed comparisons with malignant tumours of man and animals, and also treats the production of new organs in crown gall as comparable to the embryomata and teratomata of the animal pathologist. Further observations and comparisons on these lines have been made by Jensen, both by inoculating crown-gall bacteria into beets and also on certain tumours of this plant from which it is not clear that *Bacterium tumefaciens* can be obtained. Jensen has successfully transferred the latter tumours by grafting between yellow and red forms of Beta; these grafts show little indication of any real infiltration of the normal tissue.

In attempting to form a critical estimate of this disease, and of the comparisons that have been made between it and pathological processes in man, we must take into account the normal construction and mode of growth of the affected portions of the plant as contrasted with animal tissues; the reactions to wounding in plants; the reactions of the plant to various parasitic organisms; and the relation of tumour formation in the plant to wounds and parasites. It will be found that these problems are connected, and that collectively their consideration puts us in a better position to appreciate the reactions of the vegetable tissues to the crown-gall bacterium.

The absence of a nervous system, and, still more important, of anything corresponding to the circulatory system of the higher animals, must always be kept in mind when considering disease reactions in the plant. Along with the absence of blood and lymph we must note the special type of the tissues in plants due to their being composed of cells with the protoplasts enclosed by cell walls. Another important difference from the higher animals is found in the continued development of most plants. The formation of new tissues and organs continues throughout life at the growing points of the stems and roots. The enlargement of the parts thus laid down, and the separation of such organs as the leaves of the bud, takes place as their cells become vacuolated in attaining their mature size and condition. In addition to the activity of the primary meristems at the growing points a continuous production of new tissues proceeds from layers of meristematic tissues within the plant. The most important of these layers is the cambium, between the wood and the bast to which secondary thickening is due.

Many of the features of the reactions in crown gall depend on these general characteristics of growth and construction in the plant. A point to which attention may be specially directed is that the distance over which the effect of an inoculation is manifest may be almost entirely due to the subsequent enlargement and separation of the parts as the bud expands into a shoot. This will be seen to have an important bearing on the distance separating the secondary from the main tumours.

The condition of correlation between the parts of the whole organism controls in the plant, not merely the balance of the mature tissues, but the production of new organs and the arrangement of these and of their tissues. This correlation becomes evident when it is disturbed in any way, and plays an important part in the pathological reactions to wounds or parasites. The removal of parts of the plant—for instance, of the terminal bud—may so alter the balance of the whole as to cause dormant growing points to become active or others to change their reaction to the environment.

When the tissues are relatively mature there may be little reaction at the wound itself, save some drying of the surface or the production of a protective layer of cork. In other cases a marked alteration of growth indicates the disturbance of the normal correlation of the tissues. This is best seen when the latter are immature, but wounding may lead to a rejuvenation of the adjacent living cells even when they form a mature tissue. Thus in the wound reactions of stems of dicotyledonous plants living cells of the cortex and pith proliferate to form a new growth of wound-callus, but the main development of this is from the meristematic layer of the cambium. The effect may extend some distance back from the wound, and the callus itself may not only close the wound but may become the seat of new growths such as shoots or roots. The cells of the callus become organized as permanent tissue, which often has an irregular or atypical arrangement, as is best seen in the characters of wound-wood.

A number of the features of crown gall will thus be seen to be paralleled in wound reactions of plants. The causal influence of *Bacterium tumefaciens* is, however, shown by the fact that callus-like galls of considerable size develop when

there would otherwise be only a relatively slight wound reaction in the particular plant.

The tissues of the normal intact plant are free from foreign organisms except in certain cases of symbiosis, which for our present purpose can be grouped with parasitic diseases. The effect of intrusive parasitic organisms differs in accordance with the specific nature of both host and parasite. There may be little or no evidence of reaction on the part of the host; this is especially the case when the affected parts are relatively mature. Marked reactions are usually associated with incompletely differentiated tissues or with meristems, whether primary or secondary.

The numerous new growths or galls on plants due to parasitic animals can only be mentioned without entering into details as to their variety. They always involve more or less wounding, but the effect of the secretions and excretions of the animal parasite in the gall is predominant. A detail of some interest to animal pathologists is the production of multinucleate giant cells in relation to the presence of parasitic cell-worms in the roots of various plants, in other galls, and in crown gall itself. The common oak-apple may be mentioned as one example of insect galls on account of the similarities which it, like some specimens of crown gall, shows to the development of wound-callus on the end of a cut stem. In this case the terminal bud of the oak is, in fact, considerably wounded by the gall-insect before she lays her eggs. The further callus-like growth which encloses those in the soft tissues of the gall is mainly due not to the wounding but to the irritation of the parasites.

Marked reactions to parasitic organisms without the complication of wounding are found in the case of vegetable parasites. Striking examples are afforded by the wart disease of the potato, where axillary buds are affected by *Synchytrium endobioticum*, and by club root, where the cambium and secondary tissues of the cabbage or turnip are stimulated by the presence of *Plasmodiophora brassicae* within the cells. The alterations of form of the host-plants due to uredineous fungi affecting the primary or secondary meristems or immature tissues can be contrasted with the relatively slight reactions due to similar fungi affecting more fully grown stems and leaves. In some cases, as in certain fern leaves affected by *Exosaccaca*, new leaf-like growths result from the presence of a fungus.

Many bacterial diseases of plants are of the nature of "rots" with little or no reaction, but in the bacteriosis of the olive tree we find irregular tumour-like growths with the causal organism evident in cavities. The well-known root tubercles of the Leguminosae afford another example of a marked reaction due to the intrusion of a bacterium, the presence of which is in this case beneficial to the host.

In the various cases of irritation by animal or vegetable parasites resemblances to crown gall are evident. This is of course not surprising, since we know that this disease is due to the influence of a parasitic bacterium.

Tumour-like growths in plants are in many cases, as will be evident from what has been said above, the result of the stimulation due to parasitic organisms. Others are due to wounding or are associated with the wound-callus formed as a reaction to this. Some of the globular woody tumours found in the cortex of trees are of this nature, the wood developing from layers of cambium formed around groups of cells of the bark. Other tumours, superficially like these, have their cambium derived from that of dormant buds which may lose their connexion with the wood of the trunk. The latter examples have long been recognized as giving a point of comparison in plants to Cohnheim's explanation of the origin of animal tumours. True tumours, apart from wounding or the presence of parasites, are, however, rare in plants, and comparison with animal tumours is thus limited. In all tumour-like growths in plants the tissues are liable to be more or less atypical in their histology.

In the light of this brief survey of some other pathological reactions in plants crown gall appears as a particular case of a callus-like tumour growth following on the introduction by a wound of *Bacterium tumefaciens*. There is no doubt that the resemblances between the appearances presented by sections of some of the tumour-like growths in this disease and animal tumours are striking and may well interest the human pathologist. To what extent even in the case of this particularly favourable plant disease it is wise, safe, or useful to make specific comparisons with particular pathological processes in man is, however, open to discussion.

How closely the comparisons between crown gall and

reference to Erwin Smith's papers and his recent *Introduction to Bacterial Diseases of Plants*.

The importance and interest of the pathological processes in crown gall fully justify their comprehensive study which we owe so largely to the work of this investigator. It does not appear possible, however, to accept on the evidence before us all these direct comparisons with malignant tumours in animals, nor to draw conclusions as to the etiology of the later from the undoubted facts as to *Bacterium tumefaciens* being the cause of crown gall.

The cell multiplication and the imperfect differentiation of the resulting tissues have been seen to be common to a number of disturbed growths in plants. The tendency to a production of new organs from the crown-gall tumour is paralleled in the case of wound-callus, galls, and some parasitic diseases of plants. There is real danger of being misled by a name if we speak of those new growths in this plant as teratomata or embryomata. In regeneration in plants the formation of a complete plant from a somatic cell or group of cells is common. The conception of embryomata tumours in animals involves the early distinction of the germinal layers and of somatic and reproductive cells; there is no strict parallel to this in plants.

Passing from these more general features to the peculiarities of crown gall which have been made the ground of special comparison with malignant tumours we find that some of the more critical facts are uncertain and in need of re-investigation. One of these concerns the actual place occupied by the bacteria in the crown-gall tumour, from which there is no doubt they can be obtained. In earlier accounts Smith figured bacteria in small numbers in the cytoplasm of the tumour cells. More recently he has stated that the bodies thus demonstrated are not bacteria. He still, however, assumes that bacteria are present within the cells, and are these liberating products which lead to the tumour growth. As the matter stands there seems no evidence for arguing from crown gall in support of intracellular parasites in malignant tumours. The uncertainty as to the position of the bacteria in the active tumour evidently bears on the further hypothesis of Jonsen that the bacteria may disappear, leaving the cells with the abnormal type of growth impressed upon them.

What thus comes, as the real ground for comparing crown gall with malignant animal tumours, to the power of intrusion of the tumour tissue into the normal tissues of the plant and of their producing secondary tumours at a distance. The question of actual intrusion, as distinguished from extension of the morbid process to adjoining cells, requires critical re-investigation. There is no doubt as to the existence of what have been termed secondary tumours, connected with the main tumour by a more slender strand of tumour tissue. It is by no means clear, however, in what sense or degree these represent intrusions, and a fuller explanation of their mode of origin is required, due allowance being made for the extension of the parts by growth from their condition at the time of infection.

One feature of the secondary tumours in the leaf on which stress has been laid is that they appear to repeat the structure characteristic of the stem, where the main tumour is situated. The radial arrangement of the vascular tissues in the secondary tumour and the tumour strand does not, however, appear to involve this interpretation. It cannot be taken as corresponding to the repetition of histological characters peculiar to the primary tumour in secondary malignant tumours in the animal body.

Crown gall, as one of the plant diseases most fully studied from this point of view, thus appears to bear out the apprehension expressed at the outset as to the soundness of detailed and direct comparisons between particular diseases in animals and plants. Doubtless, as our knowledge of normal protoplasm increases, and as pathological processes are traced back to changes in the cells and their protoplasm, and fundamental common features of disease in plants and animals will become more and more evident. Though this aspect of the subject cannot be pursued here, it is of interest to note that Erwin Smith's studies of crown gall have led him to consider and experimentally attack such general underlying problems.

It will evidently be advantageous for a student of plant pathology to study some animal diseases, and conversely for a human pathologist to pay attention to some diseases of plants. Such studies must, however, always be conducted in the light of the differences in morphology and physiology which characterize animals and plants. The value of taking

plant diseases into consideration in human pathology (and in passing one may add of including some plant pathology in the education of the medical student) comes rather from this widening of outlook than in the form of direct inferences from the one subject to the other. To the philosophical human pathologist the study of some plant diseases may well be light-giving, and it is perhaps better not to expect it to be fruit-giving.

"*Et lucifera experimenta, non fructifera quaerenda.*"

DISCUSSION.

SIR CLIFFORD ALBUTT said that he was ashamed to lay before the Section more general considerations, in contrast with the solid results contributed by his expert colleagues. The President kindly called upon him to speak because he had taken a great interest in comparative pathology for many years. When President of the Section of Medicine, in 1882, he had pointed out the need of the Comparative Method in the study of disease; and again, in the Bute Hall of the Glasgow University, in the address on Medicine in 1888, he had urged the same message. At last, by the cordial co-operation of the President of this morning, the importance of the subject had not only been emphasized, but had also been fully vindicated, by the papers they had heard during the forenoon. Sir Clifford urged that no scientific subject could progress without the comparative method; history, philology, anatomy, physiology, etc.—even religion—owed much of their accumulated and systematized knowledge to the method. Outside the nosology of Man there were many workers—workers on the diseases of animals and of plants; therefore there was the less excuse for neglect of comparative methods by human nosologists. This supineness inflicted the same sterility upon the workers in other fields, such as veterinary medicine, plant pathology, and so on; each body of experts was working in isolation.

In his masterly paper Professor Lang had warned the students of Comparative Pathology against the snare of false analogies; but might not the adjective be left out? Arguing by analogies had been the bane of medicine from the earliest times. We had now to go beneath analogies and similitudes to underlying affinities, which indeed were often far from apparent. Even in the comparison of proper names—for example, surnames and names of places—we found every day the errors of derivation from appearances and analogies; when their history was traced in ancient records such derivations often proved to be false. We must be careful then in making direct cross-references, but rather trace genetic affinities from leaf to twig, to branch, to stem, until we reached a general view of the development of the processes concerned. It was true, as Professor Lang had said, that this method made us go a very long way back; but he had himself carried his striking comparisons back to a remote geological record. Furthermore, the biologist must be continually conversant with the properties of colloids, and so farthor back again to physics with its laws of interface actions, adsorption, osmosis, and so on. We must seek for origins, however far back they may be. To take a simple modern and practical instance: Whence comes the healing virtue of cod-liver oil? As Dr. Hjort had shown, to find an answer we had to go back to certain marine algae which formed a part of the plankton on which fishes feed. It was in these lowly vegetables that the vital agents seemed to be created which gave their virtue to the oil that might be extracted from the livers of many fishes, but chiefly of the cod. The same result was seen in the virtue of the sprouting seed, of the pea, for instance, as contrasted with the impotence of its dry state.

Again, one of the mysteries of the animal body was the part played in metabolism by certain salts—by calcium, for example. The simplest forms of life might indicate the nature of this and of many other processes, which in highly developed animals were too entangled to be tracked out. The absence of a nervous system, and indeed of a definite circulatory system, might leave open to the observer the beginnings of the most essential principles or rudiments of vital processes. Thus the implicit capacity for fever could hardly emerge without the thermotaxy of a nervous system, whereby a local morbid change became subordinate to the balance of systemic forces. Our purpose was to detect the behaviour of protoplasm under an infinite variety of conditions, not here and there only, in several closed compartments. We knew, on physical, chemical, and biological grounds, how extremely slight were the structural differences which might issue in

extremely different functions; as in adsorption, catalysis, chemical substitutions, immunities, and so on. When we get some command over such slight differences we should gain large powers over the perversions of molecular construction. A small rudder might control a very big ship. Morbid changes by no means always came about by gradual augmentation of differences, but by leaps and bounds, as musical flames fitfully responded to scales of vibration. Therefore clinical "Types" could form no basis for nosological classification. Besides, there was mimicry in disease, under which guises must be detected those processes which were alike at the core (*αισθησις ὅμοια*). An internal change which converted a benignant or anabolic process into one of destructive malignancy might be very small; for instance, cacodylic acid, which was soluble and contained 70 per cent. of arsenic, was non-poisonous; and again, the non-poisonous cyanides and carbamides exhibited vital differences generated by slight molecular dislocations. Great secrets, then, might lie in the simpler play of uncomplicated principles, could we but get down to such conditions. As Professor Welch had said to the speaker in a recent letter, "we need a mode of research in which the first word shall be Comparison." But in such research we should be hampered if physicians would persist in supposing diseases to be "clinical (or other) entities"; they might as well attribute them to demons.

Of the tremendous importance of the study of diseases of animals or plants which were transmissible to man we had learnt much again from the contribution of Professor Hobday; into that utilitarian side of Comparative Pathology—pressing as it was—the speaker could not then enter; he had to keep to his own side—the research side—of the problems, a side on which he felt less incompetent to speak. He desired to insist upon the genetical, the historical, the geographical, the experimental methods. For there could be no complete system of therapeutics until the science of Comparative Nosology—a science as yet hardly recognized—until the genetic affinities of diseases, their origins, parent stems and alliances, as well as their issues, were worked out.

Note.—These reflections were subject to exceptions, such as the brilliant work of Sir John Bland-Sutton (*Introduction to General Pathology*, etc.) and of a few others. Some passages of the present argument were quoted from the speaker's two former addresses.

Professor S. H. GAIGER (Glasgow) said: Professor Hobday's list of animal diseases communicable to man is sufficiently long without any additions, but to it there can be added certain of the African trypanosomiasis where the rôle of animals in the spread of the human disease has been much discussed in recent years. It is questionable whether in his list there should have been mentioned as a possible danger to human beings the *Bacillus abortus*; more probable is it that it should have been left out. It is a matter for much satisfaction that science has shown the method by which glanders and rabies can be stamped out. The recent outbreak of rabies in this country shows clearly that the advice of the veterinarian with regard to visitations of disease is infinitely preferable to the advice of the lay administrator. The country has to buy its experience in such matters, and if the recent outbreak of rabies with its 179 persons bitten has taught Britain this fact it was worth it. Animal diseases cannot be got rid of in Britain without a knowledge of veterinary pathology any more than human diseases can be combated without a knowledge of the pathology of human diseases. Though glanders and rabies are practically stamped out in Britain they are rampant in many other countries, including some countries within the British Empire. In the case of anthrax we are dealing with a more insidious disease. The causal organism is a sporulating one, and therefore capable of living for presumably indefinite periods apart from the animal body. Official control of such a disease lessens the risk of bacterial multiplication from actual cases of anthrax, but at present gives no protection against spores brought in animal products from abroad. There is no doubt that progress against anthrax will be slow but sure, and that concerted action will in time eradicate the disease. It is not lack of pathological knowledge that prevents the eradication of bovine tuberculosis. We have a reliable diagnostic agent in tuberculin, and we are dealing with a non-sporulating organism which cannot live indefinitely away from the animal body. We have all the means at our disposal to enable us to stamp out tubercle from our herds except funds and organization to allow us to carry on. The matter is a very serious one, but only a spasmodic effort or two is being made

at present instead of the necessary campaign. The tubercle bacillus makes no spasmodic effort, it is war spread broadcast, and measures to cope with it must be correspondingly extensive.

The medical man and the veterinarian can both derive great benefit from the study of comparative pathology apart from the communicable diseases. Take, for example, diseases caused by the pathogenic anaerobes in man and animals. Up to the war period the position of our knowledge of these infections was one of almost hopeless confusion. None knew what really was the correct account of the biological characters of any pathogenic anaerobe. Some gave their descriptions from pure cultures, others from impure cultures, and the disparities were by no means always the same. The war period brought with it the necessity for the study of wound infections. We were found totally unprepared for the specific treatment of gas gangrene, and prior to making antiserums for the treatment of this condition it was necessary to suffer delays from the indispensable preliminary bacteriological study of the causal organisms. This delay meant the loss of many valuable lives. It has fallen to me in the last few years to investigate certain anaerobic infections in animals, and particularly braxy in sheep. Braxy is an example in animals of a pure infection with an anaerobe. It is true it is not a skin-wound infection. It is a stomach-wound infection, not a wound in the usually accepted sense of the term but an injury from the lowering of the tissue defences from chills, from frosted food, etc., and the anaerobe is enabled to gain entrance. It invades the system in pure culture. Bacteriologists studying gas gangrene spent much time purifying the anaerobes from that condition, and one way they did so was by passage of the bacilli through the animal body; yet here in braxy in the sheep, had it been known, was to be found one of the most important of the gas gangrene organisms invading the system in pure culture from the stomach, leaving other anaerobes and aerobes behind. It is, in fact, a natural purification of this bacillus by animal passage, but no one knew of it. I believe that time is going to show the pathogenic anaerobes to be of vast importance to the veterinarian. My investigations into braxy will be published in a few weeks, but that is only one instance. There are others. In peace time anaerobic infections in wounds in man are negligible in number. In war time it is quite the reverse. In animals many do not yet realize the extent of such infections. Had a thorough knowledge of anaerobic infections in animals been available before 1914 the medical scientist would have been greatly helped and serum treatment would have been available early in the war instead of just as the war was closing. As it is, the veterinary pathologist has been greatly assisted by the war-time studies of the human pathologist. Let us hope that the day is not very far distant when veterinary research in Britain will be directed by a Veterinary Research Committee, after the manner in which research into human diseases has been so ably assisted by the Medical Research Council.

Mr. WILLIAM B. BRIERLEY (Rothamsted Experiment Station) said: May I state at once that I agree fully with the greater part of what Professor Lang has said? The unbridgeable gulf between the morphology, anatomy, and physiological processes of animals and plants resulting from the complete divergence in their evolutionary sequences must be recognized. There is in animals nothing comparable with the rigid-walled cells of plants, and in plants nothing comparable with the blood vascular system, the lymphatic, alimentary, nervous, muscular, and skeletal systems. It is these characteristic features that give rise to and make possible the specific pathological responses associated with disease. Occasionally interesting but purely superficial general parallels exist, but to find exact analogies in development and structure, and even more to trace exact correspondences in the details of the morbid histology of diseased host tissues of animals and plants, and to reason from one to the other is to falsify and confuse every issue. These differences are fundamental, and comparative investigations can only have value if they are borne arduely in mind. Within recent years detailed comparisons have been made between that very remarkable disease of plants, crown gall, and malignant animal tumour. Professor Lang has indicated that in his view this comparison, except along the most generalized lines, must be regarded with much circumspection, and on the whole I would associate myself with Professor Lang. One point on which,

however, I would definitely reserve my opinion is whether the tumour strand is an infiltrative tissue. I have had the very great privilege of examining many of the wonderful series of specimens and preparations of Dr. Erwin F. Smith, to whom we owe all our knowledge of crown gall, and as I remember the microscopic appearances I find it difficult in certain cases to interpret the development of the tumour strand as other than an infiltration into foreign tissue. Secondly, Professor Lang referred to the absence of infiltrative development in the case of Jensen's beet tumour grafts. Their absence here would not appear to me to be conclusive for I think that on the whole such developments are hardly to be expected in such complexes. The conclusion to which I am drawn from a comparative review of diseased states in animals and plants is that as regards the host tissue responses there is little if anything in common save the most general reaction of wound healing. There are, however, many other aspects of pathology, and I wish to spend a few minutes dealing with certain of these.

As in animals and man, so in plants many diseased states are due to the operation of environmental factors, such as malnutrition, light, temperature, humidity, specific toxic agents, and so forth. Is it here that we shall find greater scope for comparative studies and more exact and detailed analogies? A broad survey of the evidence does not lend hopeful augury, and save in the most generalized pathological reactions and perhaps in regions of protoplasmic response and cell chemistry, to which we have as yet hardly penetrated, the two kingdoms appear to be remote from each other. Most of the diseases, however, to which we, as pathologists, direct our attention are caused by living parasites—bacteria, fungi, protozoa, myxomycetes, helminths, and arthropods of various sorts. I will say at once that it seems to me that it is in the comparative study of these organisms that animal and plant pathologists find their most intimate and real contact, for it is only in the full understanding of the causes that the rational control of the effects can be brought about and a solid foundation laid for future progress. May I in a few words indicate what are to me the most salient aspects of this point of intimate contact?

A knowledge of the structure of any particular pathogen and of related types is essential as a basis for classification and nomenclature. It is surely evident that where animal and plant pathologists are dealing with like groups, common genera, and occasionally even with the same species, that similar systems should be adopted, comparative studies made and the results pooled.

Again, related species frequently have similar developmental phases in their life cycles, and as wide and intensive a knowledge of life histories as possible is a fundamental part of the mental equipment of any pathologist. If life history studies are to have any real value they must be comparative.

A third aspect in which the value of comparative investigation seems to me so obvious as scarcely to need comment is in regard to the physiological qualities of pathogens. All problems of virulence, of disinfection, of invasive power by enzymatic or mechanical action, of physiological classifications and so forth, are essentially the common ground of both animal and plant pathologists. The fact, for example, that bacteria commonly found in the soil can oxidize phenol and cresol is of vital importance to the animal pathologist.

A fourth and very important aspect of study which can only be carried out in a comparative way is that of the genetics of micro-organisms. Problems of adaptability, modification, and mutation, the scope and permanence of these changes and their relation to the immunity, resistance, or susceptibility of specific host tissues is vital and common ground to all microbiologists. Perhaps I may be allowed to illustrate by one example. Physiological classification is based on an assumption of the permanence of certain physiological qualities; vaccine and serum therapy is based on an assumption that certain physiological qualities can be permanently changed; breeding for disease resistance is based on an assumption that certain physiological qualities are unchangeable and so forth.

A further aspect of very great comparative interest is in the geographical distribution of micro-organisms. Very little is yet known of this subject, but it presents undoubtedly a very wide and deep field for comparative study. An aspect of pathology which, from the animal point of view, is very difficult of direct experimentation concerns epidemiology. This is an easy and almost untouched field in plant pathology. It is, however, obviously a comparatively simple matter to study

problems of the dispersion of any particular pathogenic organism among a hundred or a thousand individuals of wheat or tomatoes, etc., under standardized and controllable conditions. It would not be easy to carry out such experiments on animals or man. Finally, all pathologists, whether of the plant, medical, or veterinary persuasion, are dealing essentially with the same groups of organisms and using the same methods. Advances in laboratory apparatus and technique made by animal pathologists are applicable in botanical or veterinary laboratories and conversely.

Perhaps I have occupied overmuch time with this summary, brief though it be. When, however, one realizes the great gulf between veterinarians, medical men, and botanists and agriculturists, and the great masses of knowledge which are of vital interest to all, and should be common to all, and yet which are unknown to those not actively working in this or that particular field, I do not think I am unjustified. One aspect of disease in plants which is daily growing in importance concerns that little understood group known as "virus" diseases. A later speaker will deal in detail with this, but I wish to say a very few words on the subject. Viruses and filter passers are now well known in both animal and plant pathology, and in the latter division there is a series of hitherto unrelated diseases passing under various names which undoubtedly belong here. The host responses of plants have little in common with those of animals save that in both divisions the "carrier" problem is present. Recent investigations of certain mosaic diseases would appear to indicate that bodies similar to Rickettsia and to the well-known Negri bodies may be found in the diseased tissues. Many of these virus diseases have proved to be carried by insects (although with others this is not necessary), and in the disease known as curly-top of sugar beet there are indications that the virus passes through a developmental life cycle, one moiety taking place in the insect, the other in the plant. In any case the vital comparative interest of these diseases must be patent to all.

In conclusion, I would like to make a plea for the definite recognition of a science of medical mycology similar to that accorded to medical entomology. Only a very few years ago entomologists were not regarded seriously in medical science. What might almost be regarded as a series of lucky accidents brought entomology into the very front line of medical research, and led to the recognition of medical entomology as a definite science of primary status. University chairs were founded, opportunities for research and teaching were given, and the value that has resulted is incalculable. Equally necessary is the recognition of medical mycology with similar opportunities for research and teaching. Medical mycology would give scope for that intimate contact between veterinarians, medical men, botanists, and agricultural bacteriologists, and one might even hope that thereafter the fungi pathogenic to animals and man would receive adequate and critical study. I venture to think that the first university or medical institution founding a research and teaching school of medical mycology will have taken a vast forward step in medical science.

May I in a few words summarize the points that I have wished to make? There is little that can be helpful, and there are great possibilities of confusion in making detailed comparisons of host tissue responses in plant and animal diseases. There is a vast field for common study of the great groups of micro-organisms. There is much need for common meeting grounds and the utmost value can be obtained from an intimate exchange of facts and points of view. There is vital need for the recognition of a science of medical mycology, and this meeting would be memorable if it led to such a foundation.

SOME CHARACTERISTICS OF THE VIRUS DISEASES OF PLANTS.

BY

E. J. BUTLER, C.I.E., D.Sc., M.B.,
Director, Imperial Bureau of Mycology.

The diseases of plants caused by an ultramicroscopic agent or virus appear to fall into four main classes. The largest is the group to which the mosaic disease of tobacco, first shown to be caused by a filtrable virus in 1892, belongs. The diseases in this group can be transmitted to healthy plants by grafting, in most cases (perhaps always) by sucking insects, usually by inoculating with the expressed juice or crushed

tissues, and occasionally through the seed. There are no definite necrotic lesions, except in rare cases where necrosis of the parenchyma cells has been observed. They are not usually fatal, though often very harmful.

A second, small, group consists of diseases of which peach yellows is the type. Transmission has only been effected by grafting, but natural infection takes place in some unknown way, perhaps by insects. Transmission by inoculation with the juice or crushed tissues or by the seed has not been accomplished. No specific necrotic lesions are caused, but the cases are fatal.

A third group comprises the forms of variegation which can be transmitted to normal green plants by grafting. The affected plants are somewhat less resistant to unfavourable conditions than those that are normal, but the disease (if disease it can be called) is of a very mild type. Natural infection is not known.

Finally, there is a small group resembling the mosaic diseases in many respects, but characterized by definite necrotic lesions in that part of the vascular strands through which the elaborated food is conveyed to the growing or storage parts—the phloem. This group can be transmitted by grafting and also in some cases by insects, but not, so far as is known, by juice inoculations or through seed.

Transmission.

In all the cases investigated transmission can be effected by causing organic union between the tissues of a diseased and healthy plant, as by grafting or budding. In no case is mere contact sufficient. The next most general method is transmission by insects, this being common in the mosaic and phloem-necrosis groups, and possible, though not proven, in the peach yellows type. Transmission by inoculating with the juice of infected plants is only certainly known to occur in the mosaic group (much the largest). Transmission through the seed is rare, but has been fully established in certain mosaic diseases.

In transmission by grafting not every variety of plant that can be successfully grafted can be infected, though some of these diseases have a wide range of hosts. Sometimes, also, the virus is transmitted, but the new host shows no symptoms other than the ability to transmit the disease with full virulence by grafting on a susceptible host. Thus the phenomena of immunity and of "carriers" are known.

In transmission by insects usually there is no evidence that the insect is a necessary secondary host. Infection will occur if the insect is placed on a healthy plant immediately after feeding. In the "curly-top" disease of beet, however, infection cannot be conveyed for some time after feeding (four hours at high temperatures, up to forty-eight hours at lower temperatures). There is some evidence (as in several other allied diseases) that the infective agent is not always taken up with the plant juices by the insect, possibly because it is not always in a stage accessible to the latter. No other method of transmission than by the insect (*Eutettix tenella*) and by grafting is known. Evidently the causal agent must be an organism possessing a definite life history in host-plant and insect.

Spinach blight can be transmitted by several different insects and by juice inoculations. The incubation period in the plant varies according to the age of the plant and of the insect transmitter. The infective agent is hereditary in the insect up to at least four generations. The juice of infective aphids is infectious.

Transmission by inoculation with juice or crushed tissue has been most fully studied in the tobacco mosaic. The virus is present in all parts of the plant except the embryo of the seed. Infection can be produced by inoculating any part of the plant after abrading the cuticle. The leaf hairs of infected plants contain the virus, and it can be inoculated successfully by merely cutting first infected hairs and then those of a healthy plant with fine scissors. *Nicotiana glauca* is immune to the mosaic of common tobacco (*N. tabacum*) but has a mosaic of its own, and both diseases will infect *Datura stramonium*. Carrier species are known—for example, *Physalis* can transmit the disease without showing any symptoms. Some species of aphids transmit readily, others fail though they feed and multiply on the plant.

In many mosaics the crushed plant tissue is more infective than the juice, but insects are often better than either. In some the virus is limited in distribution, and does not reach the root, for instance. In a few cases biting insects (for instance, *Diabrotica* beetles) can carry infection.

Passage of the Virus within the Plant.

There is a good deal of evidence that the virus is conveyed chiefly through the phloem. This is practically the only tissue that shows necrosis in certain of these diseases. The most usual transmitting insects are aphids, and it is now known that many of these feed chiefly or exclusively by sucking the juices from the phloem. Translocation of starch (effected through the phloem) is impeded in several virus diseases. Removing the bark (including the phloem) around the shoots prevents the passage of the virus in the infectious chloroses. The failure to reach the embryo, which is such a marked character of many of these diseases, may be explained by the fact that the vascular strands terminate in the integuments and do not reach the embryo, which is nourished by osmosis from the tissues outside the embryo sac. In the cucurbits, in which mosaic is transmitted by the seed, there are special nutritive adaptations for feeding the embryo which may serve to explain its infection.

The passage of the virus is slow in the tobacco mosaic, where it may take over three days to traverse a leaf and its stalk. In cucumber mosaic a case is recorded where it took nine hours for the virus to traverse thirty inches of stem in an upward direction.

In the infectious chloroses there is evidence that though the virus may be distributed throughout the plant it only multiplies in the chlorotic areas. If these are removed the plant will ultimately give normal green leaves. But the virus persists in a latent condition in the dormant buds of such plants, and if these are forced into growth they give chlorotic shoots which reinfect the new growth of the whole plant.

Properties of the Virus.

The virus of tobacco mosaic filters through most porous filters. In one case filtration through the Chamberland filter gave 91 per cent. infection, through the Berkefeld normal 63 per cent., the Berkefeld fine 47 per cent., and the Kitasato 40 per cent. It is retained by the Livingstone atomometer porous cup and by seven-eighths of an inch of powdered talc. The whole of the virus in infective juice is carried down with the precipitate from 45 to 50 per cent. alcohol or with an aluminium hydroxide precipitate, without losing infectivity. Antiseptics give irregular results, mercuric chloride being sometimes less effective than copper sulphate for instance. Heating to 70° C. destroys the infectivity of some viruses, others may survive 90° C. Dried infective leaves may retain 100 per cent. virulence after three years, and bottled juice up to fifteen months, even when it putrefies. Evaporated juice is less resistant. Dilution to 1 in 1,000 does not reduce the infectivity, and 1 in 10,000 does not destroy it. Cucurbit mosaic virus is much less resistant than that of tobacco mosaic, and may not survive keeping for even a couple of days.

The optimum temperature for the activity of the tobacco mosaic virus, as judged by the length of the incubation period, is 28° to 30° C. and the maximum near 36°. No symptoms appear when cooled sufficiently to check growth of the plant or heated above 36°, but they reappear when normal temperatures are again used. In certain areas in Canada infected potato plants show no symptoms and give almost normal yields, so that climate may make a plant become a "carrier" of its own virus.

Only quite recently have bodies that may possibly be organisms been definitely observed in the cells of infected tissues. In the maize mosaic and that of *Hippeastrum*, Kuukel of Hawaii has seen bodies which he compares with the Negri bodies of rabies or with *Cytoryctes variolae*, but which from his figures also resemble Rickettsia in certain stages. In tobacco mosaic, Palm of Java has just reported the presence of bodies agreeing in every respect with Lipschütz's "Strongyloplasma" or the "Elementarkörperchen" of v. Prowazek, and in another form with Guarnieri's bodies (Cytoryctes). Neither author refers to Rickettsia, but there would seem to be evident resemblances.

Though the first demonstration that disease can be caused by a filtrable virus was made in a plant disease—tobacco mosaic—human pathologists have advanced the study of the possible causative agents beyond the stage reached by plant pathologists. The latter may, however, claim to have been among the earliest to have convicted insects of playing a primary part in natural infection; they have proved that these diseases can be hereditary in host-plant and in insect; and on the experimental side, owing to the naturally greater ease of experimenting with plants, have made them amongst the best known diseases. They have shown that the plant

cuticle presents an impassable barrier to infection; that a saprophytic life of the organisms is highly improbable; and that they are often so closely associated in some way with the living tissues that infection is only possible when organic union between diseased and healthy tissues is effected. Finally, they are demonstrating the remarkable effect of the environment, especially temperature, on the course of some of these diseases.

DISEASE RESISTANCE IN PLANTS.

BY

F. T. BROOKS, M.A.,

University Lecturer in Botany, Cambridge.

As in human beings, many diseases of plants are caused by parasitic organisms, but whereas in man the parasites are chiefly bacteria and protozoa, in plants most pathogenic agents are fungi. Among men and women great differences in susceptibility to various diseases are manifest, and there are in most of us individual diversities or idiosyncrasies as regards reaction to disease. This is perhaps an expression of the much greater complexity of organization in man than in even the most highly developed plants. In plants of the same kind these individual differences as regards disease are much more obscure, and probably do not exist to anything like the same extent as in man. Thus two wheat plants under uniform soil conditions in the same field will react to attacks of rust fungi in identical fashion. On the other hand, all cultivated plants exist in innumerable races, and these do show marked differences in susceptibility to specific diseases. These races of cultivated plants are perhaps comparable genetically to the races of mankind, so that the difference in degree of attack by rust exhibited by two kinds of wheat may be compared with a differing susceptibility to some common malady exhibited by the white and the negro races; the genetic constitution of man, however, is so much more complex than that of the higher plants that a strict parallel cannot be drawn.

It is a matter of common observation to cultivators that different varieties of the same cultivated plant show marked differences in the power of resisting certain parasitic diseases. Thus one kind of rose will be badly attacked by mildew and another closely related variety, growing under the same conditions, will remain practically free from attack. Again, one kind of apple tree will show extreme liability to canker, while another, side by side with it, will remain entirely free from this disease. There must clearly be some constitutional or genetic difference between these closely related plants to account for such phenomena.

As to the actual causes of the immunity or marked degree of resistance to disease in such plants we know as yet very little, although inklings of the truth have been discovered in certain directions. It is already known that much of this so-called immunity is really disease escape—that is, through some slight structural peculiarity or divergence in mode of life on the part of the host, the germs of disease are unable to establish themselves therein, with the consequence that ill health is avoided. In such plants there is no active resistance to parasitic attack. Thus it has been shown in America that if a tomato fruit has a skin which is strongly cuticularized it remains free from attack by the fungus *Macrosporium tomatum*, whereas if the cuticle be thin the fruit is readily attacked. Structural differences of this kind also often account for a fungus attacking one part of a plant and not another. Thus the petals of flowers readily fall a prey to the spores of *Botrytis cinerea* under moist conditions, whereas healthy green leaves of the same plant in the same environment remain unaffected by these spores. This is partly because the petals, having practically no cuticle, allow of the exosmosis of nutritive substances to the fungus from the interior of the host, thereby causing stronger growth, and partly because the thinner cuticle is a less efficient barrier to the fungus than in the leaf. Another example of disease escape is shown by early varieties of potatoes, which in this country are usually free from attack by blight. It is not that these varieties are immune to the fungus *Phytophthora infestans*; they remain free from disease because they mature before spores of the blight fungus are available to cause infection. Again, early or late sowing may enable cereals to escape certain smut diseases which infect the seedlings, because of the different temperature conditions favourable to host and parasite respectively.

A specific example of the profound effect of the influence of temperature upon the incidence of a plant disease may be given. In the northern part of the United States a certain smut fungus, *Urocystis cepulae*, causes a common and serious disease of the onion, whereas in the southern States the disease is unknown, although the same varieties of onion are grown. The factor determining this difference in the occurrence of disease is the soil temperature, it having been shown that a temperature of 29°C. and above during the critical period of growth completely inhibits infection.

On the other hand, the host does sometimes actively resist penetration by a parasitic fungus, and there is definite knowledge of some of the phenomena accompanying this resistance in certain of the rust fungi which attack cereals. Sometimes the rust fungus attacks the host so feebly that haustoria—the absorbent suckers of the fungus—cannot be established in the host cells, so that the parasite quickly dies. In other cases the parasite attacks the host so vigorously as to kill the cells in its immediate vicinity; in this way the fungus surrounds itself with a barrier of dead cells which it is unable to penetrate, for in the rust fungi it is only when a quasi-symbiosis is established with the host that the parasite flourishes. In the latter example the immunity to attack is really due to the parasite attacking initially so vigorously as to defeat its own object. Immunity of this kind is sometimes said to be due to a hypersensitiveness on the part of the host. This phenomenon is by no means rare in cereals, and most of the varieties of wheat immune to rust attack owe their immunity to this hypersensitiveness. Again, with some varieties of cereals practically immune to mildew (*Erysiphe graminis*) the resistance can be broken down by reducing the vitality of the host—for example, by subjecting the leaves to the vapour of chloroform or ether.

If closely related varieties of wheat, one of which is susceptible and the other immune to yellow rust, are hybridized, it has been shown recently by Biffen and others that susceptibility and immunity behave as a pair of Mendelian allelomorphous characters segregating sharply from one another in the second and subsequent generations. In this example susceptibility is dominant to immunity, but with other parasitic fungi there is evidence that immunity may be dominant to susceptibility. Apart from certain diseases, such as colour-blindness and haemophilia, which are sex-linked in their inheritance, I know of no human diseases, certainly none of parasitic origin, susceptibility to which is transmitted hereditarily according to Mendel's law. It may be that in man susceptibility to disease depends upon a multiplicity of factors in the Mendelian sense, whereas in the above examples taken from plants only a single factor appears to be involved.

In this connexion it must be pointed out that the interactions of host and parasite resulting in immunity are purely local in effect, and any antibodies formed during the struggle are not transmitted to other parts of the plant, there to confer immunity. With few exceptions parasitic attack in plants is relatively localized, the parasite only gradually enlarging its domain by progressive advancement. In the higher plants there is nothing comparable with the blood stream of vertebrates, the circulation of sap being essentially different in important respects; hence antibodies formed in response to parasitic attack in one part are not readily carried to other parts. On the other hand, fungi inhabiting the vascular systems of plants sometimes secrete toxic substances which, carried in the sap, cause death in distant parts.

Although susceptibility and immunity to certain plant diseases are phenomena of genetic significance, it is clear from recent investigations that the expression of the genetic factor may be modified by environmental influences. Thus a wheat genetically immune or highly resistant to yellow rust may, under certain abnormal weather conditions, become quite susceptible to this parasite, but this is only an illustration of the fact that organisms in general are the result of hereditary tendencies moulded by environment. The environmental factor is, however, of particular significance as regards the incidence of plant diseases. Unlike human beings, who, within certain limits, can control their environment, plants are relatively passive and cannot control the conditions under which they live. To give one illustration: the internal temperature of man is practically constant, whatever the weather may be, whereas a plant possesses very little power of controlling its internal temperature, this being almost entirely dependent upon external conditions. One is not surprised, therefore, to learn that plants genetically highly resistant to certain diseases fall a prey to these

troubles under abnormal conditions. A few examples of this breaking down of the resistance of the host may be given. The variety of wheat known as Einkorn is entirely immune to attacks of black rust under normal climatic conditions, but during the height of the hot spell in the plains of northern India it readily falls a prey to this fungus disease. Again, agricultural experience shows that crops in general become more susceptible to fungoid disease when manured excessively with nitrogen; on the other hand, heavy manuring with potash tends to confer an additional degree of resistance to disease. Simple changes of this kind obviously exert some modifying influence upon the host protoplasm which leads to alterations in the incidence of disease. Another example illustrates a phenomenon of a more obscure nature. As is well known, commercial varieties of apples are usually grafted upon a stock of a somewhat different nature. One of the most commonly grown varieties of apples, Bramley Seedling, is almost entirely immune to the disease known as apple canker when grafted upon most kinds of stocks, but when grafted upon one particular type of stock it is so badly attacked by this disease as to be commercially worthless. There is as yet no explanation for this remarkable change.

Generally in plant diseases there is no such thing as unmodifiable immunity. In plant pathology one deals rather with examples of high resistance than with absolute immunity, and it has been pointed out that a pronounced degree of resistance may be altered to some extent by environmental influences. But there is one plant disease, and it happens to be one of serious importance in this country, in which the immunity of certain races is absolute, and, as far as is known, entirely unchanged under all conditions of environment. I refer to wart disease of potatoes due to the fungus *Synchytrium endobioticum*, which causes the tubers to proliferate into monstrous growths. There are some varieties of potatoes which are absolutely immune to this disease under all conditions, while others show differing degrees of susceptibility. Unfortunately it is not yet known why some varieties exhibit this clean-cut immunity, but as investigations are proceeding in this matter it is hoped that light will soon be thrown upon it.

Another difference between animal and plant pathology lies in the fact that no examples are known in plant pathology of the conferring of artificial immunity by inoculation of a susceptible plant with a weak strain of an otherwise virulent parasite. As mentioned above, parasitic attack in plants is usually localized, and there is no mechanism for the circulation of any antibodies which may be produced in consequence of this attack to other parts of the host plant. Plants attacked by parasitic diseases not infrequently recover, but this is no guarantee against attack again in the immediate future. Thus a plum tree suffering from silver-leaf disease caused by the fungus *Stereum purpureum* may completely recover, and then, upon this fungus being introduced again by inoculation, will readily become affected a second time.

Many plant diseases are due to a class of fungi known as wound parasites. These are peculiar in their mode of life in that they cannot infect living tissues directly, but only via dead cells. Many tree-destroying fungi are of this class. For example, one of the commonest bracket fungi, *Polyporus squamosus*, which frequently kills elm trees, is only capable of causing infection if its spores alight upon some exposed wound. The fungus, therefore, begins its life as a saprophyte and passes to the interior of the tree where all the cells are dead, still maintaining its life completely as a saprophyte. In its capacity as a saprophyte it may cause grave damage to the tree, rotting the central wood of the trunk, so that loss of rigidity may cause the tree to be blown over in a high wind. It is only after long existence as a saprophyte that *Polyporus squamosus* begins to attack the living cells of the sap-wood of its victims, when, of course, it is acting as a parasite. The higher plants frequently contain much more dead tissue proportionally than the higher animals, and with these wound parasites the actual damage inflicted on the host often concerns the dead tissues more than the living. It is impossible to speak of active disease resistance by dead tissues, although there is often exhibited a passive disease resistance, dependent upon such factors as the texture of the wood, its air content, and its chemical composition.

Where the degree of disease resistance to specific wound parasites of closely related plants differs greatly it is not yet known how much of this resistance is due to active opposition on the part of the protoplasm and how much to passive resistance dependent upon the factors mentioned above. With a wound parasite such as *Stereum purpureum*, the

cause of silver-leaf disease in fruit trees, marked differences in susceptibility are shown by closely related varieties. Thus the Victoria variety of plum is very susceptible to this disease, while the variety Pershore is rarely affected by it. Although these differences in susceptibility to disease are just as marked with wound parasites as with obligate parasites such as rust fungi, the explanation of relative immunity is probably of a considerably different nature in the two categories.

Finally, it need scarcely be pointed out to pathologists that, in plants as in man, resistance to one particular kind of disease does not imply resistance to other diseases.

PERSISTENT EOSINOPHILIA WITH SPLENOMEGALY.*

BY

STUART McDONALD, M.A., M.D., F.R.C.P. EDIN.,

Professor of Pathology, University of Durham College of Medicine;

AND

A. F. BERNARD SHAW, B.A., M.D., F.R.C.P.I.,

Lecturer on Pathology, University of Durham College of Medicine.

[With Special Plate.]

DURING the past year we have had under observation a case of persistent eosinophilia, associated with a high total leucocyte count and marked splenomegaly. The condition, so far as we can determine from the literature at our disposal, appears to be extremely rare. We have only found records of two similar cases, both in America. The present case is still under observation, and, though we have come to no final conclusion as to the etiology and nature of the condition, we have thought it worth while to record the case in the hope that others who may have observed the condition will publish their results.

As splenectomy was performed with marked improvement in the patient's physical condition, the case may have some special interest at present in view of the modern tendency to remove the spleen in cases of various "blood diseases" of unknown or uncertain origin. The existence of such a high degree of an eosinophilic leucocytosis has also given us an opportunity of making some observations on the phagocytic capacity of the eosinophiles and on the relationship of the eosinophilic cells to the formation of Charcot-Leyden crystals.

CLINICAL HISTORY OF THE CASE.

The patient, J. H., was admitted to the Royal Victoria Infirmary, Newcastle-upon-Tyne, on July 14th, 1921. We are much indebted to Mr. A. M. Martin (under whose care the case was admitted) for permission to publish the case, and for the use of the clinical records; we are also much obliged to Dr. Philip of Morpeth, who has kept us in touch with the patient since the operation. The patient on admission gave the following history:

For the last seven years he had been troubled with vomiting in the morning, but this had not interfered with his work, at which he had continued till the day of admission. His occupation is that of a hedger and ditcher, and his work being outside he had been constantly exposed to "all sorts of weather." He has never had any serious illness and has never had occasion to consult a doctor till now. He is 46 years of age. His family history is perfect; father and mother are alive and well; he is married, and his children are all healthy. He has always been rather a small eater, taking very little meat and living mainly on bacon and eggs. He is rather a spare, lightly built man, and his normal weight is about 10 stone. Beyond some slight indigestion and flatulence he states that he had nothing to complain of, but on being questioned he admitted to having felt rather done up lately, and being conscious of loss of weight he consulted his doctor five days before admission.

Dr. Philip on examination found an abdominal tumour, and this, coupled with the loss of weight and some gastric symptoms, suggested a possible malignant growth. He was recommended for admission to hospital under Mr. Martin.

On admission on July 14th, 1921, he was found to be suffering from an enlarged spleen; there was no pain. He looked in very poor condition, and was obviously ill. Careful physical examination, however, revealed very little. His weight was only 8 stone. There were no enlarged glands, and but for the splenomegaly and a marked blood change there was nothing of importance to note. A blood examination (see Table I) showed a leucocytosis of 34,000 per c.mm., and a differential count gave a very high percentage of eosinophiles (71.4 per cent.). There was only a slight degree of secondary anaemia. The blood picture did not in the

least suggest an ordinary leukaemic condition, and, though there was no evidence of a parasitic cause, the possibility of a hydatid infection was suggested, and Mr. Martin explored the abdomen on July 29th, 1921. Finding a freely movable spleen with no adhesions, he performed splenectomy. The liver looked normal and was not enlarged. No special difficulty was experienced; there was very little haemorrhage, and the patient made an uninterrupted recovery from the operation.

The details of the subsequent blood examinations will be given later, but it may be briefly stated that since the operation there has been an increasing leucocytosis, rising in December, 1921, to 92,800 per c.mm.; the percentage of eosinophiles has remained fairly constant and has risen now to 82 per cent. Together with this there was steady improvement in the patient's physical condition. He left the hospital with a soundly healed scar on August 27th, 1921. He returned again on November 10th, and stated that he was much better and was already able to do some light work; there was no enlargement of the liver and no enlargement of lymph glands.

He returned again to the hospital for examination on December 15th, and said that "he was almost himself again." He had been doing a full day's work for the past six weeks. His weight was restored to 10 stone. On examination it was noted that there was no enlargement of the liver, but there were a few moderately enlarged glands present in the posterior triangle of the neck on the left side and one similar gland above the inner third of the right clavicle. Very slightly enlarged glands could be detected at the apices of both axillae, but the occipital, epitrochlear, and inguinal groups could not be detected.

In order to report progress for the purposes of this paper he returned for a further examination on June 29th, 1922. He stated that he had not missed a day's work since he left hospital in December. His appearance, however, did not bear out his statement that he felt quite well. He was thin and pinched-looking; his weight was only 8 st. 11 lb. He said that he had an influenza cold in February, but continued to work; up till May he had a succession of slight "colds" and felt very tired at times. He seems to have had "rheumatic" pains in his limbs and the soles of his feet. There had been no return of stomach trouble, and for the past three weeks he had felt very well indeed. On examination the glandular enlargement was as in December, 1921. There was distinct deterioration in the blood condition (see Table I); there was albuminuria with casts, granular and epithelial, and some red blood cells and leucocytes in the centrifugalized deposit; no eosinophiles were detected. The faeces were examined microscopically on six occasions during the year, and no evidence of parasitic invasion of the alimentary canal was found. The general impression conveyed was that he was distinctly failing.

Blood.

Examination of stained films before operation (July 16th, 1921) showed a considerable degree of anisocytosis and poikilocytosis. There was also a slight degree of polychromatophilia and an occasional red cell with punctate basophilia. No special abnormality was noted on the part of the blood platelets; an occasional nucleated red cell was observed. The only striking alteration in the blood picture was the great number of eosinophilic leucocytes (see Table 1, B). The majority of the eosinophiles appeared to be larger than normal, though some were distinctly smaller. The nuclei appeared, on the whole, to be distinctly more lobulated than normally. A differential count of 300 eosinophiles with reference to the degree of lobulation of the nucleus was made on each occasion when the blood was examined, and the results are seen in Table II. Eosinophilic myelocytes appeared to be smaller in size than normally and only constituted 0.7 per cent. of the total count. The granules in all the eosinophilic cells were fairly uniform in size; in the case of a few cells they seemed to take the stain less intensely. In the five subsequent blood examinations following the splenectomy the above observations were generally confirmed; some exceptions, however, are to be noted.

As regards the red cells, there was a distinct rise in the number of nucleated forms (see Table 1, B). In the last two examinations megakaryoblasts were present in an appreciable amount; in the last examination there appeared to be a slight increase in the average diameter of the red cells and blood platelets seemed to be more scanty. From August 17th, 1921, it will be observed (Table I) that there is a steady diminution in the number of the red cells. In the last examination (June 29th, 1922) the diminution was still more marked. A fragility test for the red blood corpuscles made on December 16th, 1921, showed no abnormality. The coagulation time, as estimated by Boggs's coagulometer, was three and a half minutes, compared with four and a half minutes in a control. As regards the leucocytes, it will be observed from Table I that there was a steady and considerable rise in the numbers up to December 15th, 1921, when the highest count—namely, 92,800—was reached; there is, however, a slight fall in the last count (June 29th, 1922).

An examination of the differential counts shows on the whole a gradual fall in the percentage of polymorphs, with a corresponding increase in the lymphocytes—possibly the result of the splenectomy. The percentage of large mononuclears and basophiles has remained almost constant. The percentage of eosinophiles has remained much the same throughout, though it may be noted that the highest figure obtained (82 per cent.) was found in the last examination. As regards the percentages of eosinophilic myelocytes, it will be noted that it has always been small and distinctly uniform—usually about 1 per cent. On one occasion only did it reach 2.7 per cent.

An examination of films made at various times since splenectomy shows on the whole distinct uniformity, and the following points may be noted: The eosinophiles appeared to be less fragile than normally, and ruptured cells were comparatively rare. They

† In the differential counts up to December 15th, 1921, no neutrophils or basophilic myelocytes were seen, though examination of the films generally showed their presence. On December 15th, 1921, there were 0.3 per cent. neutrophils and myelocytes, and on June 29th, 1922, there were 0.3 per cent. basophilic myelocytes.

varied much in size, many being little more than half the diameter of others, while cells very much larger than the ordinary eosinophiles were common. A striking feature in many of the cells was distinct vacuolation of the cytoplasm. The granules themselves varied in size and in their affinity for eosin. In many of the cells the granules were distinctly scanty, clear areas being left in the cytoplasm, which sometimes showed a diffuse basic tint. A few basophilic granules of varying size could sometimes be observed scattered irregularly among the eosinophilic granules. The polymorphs were often observed to be staining faintly, the appearance suggesting either immaturity or degeneration. The granules varied in size to some extent, but there never was the slightest difficulty in distinguishing them from the eosinophilic cells.

Note.—Under myelocytes are included only those cells with round or oval nuclei; under the term "simple," nuclei which are indented but not distinctly lobed.

Many of the granules were poorly coloured, and some showed a faint basic tint. A few isolated white cells were observed whose nature could not be determined with certainty. The nuclei varied from a horseshoe shape to a more convoluted type. In the cytoplasm were both distinct eosinophilic and basophilic granules. Some of these may have been merely degeneration forms, others may have been phagocytic mononuclear cells.

In the last two blood examinations a few distinct neutrophils and basophilic myelocytes were seen; they never exceeded 0.3 per cent. The oxydase reaction with alpha-naphthol and paraphenylenediamine was done on two occasions. The eosinophiles were definitely positive, but the polymorph leucocytes stained poorly, and some of these gave a negative reaction.

Prolonged examination of numerous films failed to show any bacterial or protozoal parasite. A blood culture on June 29th, 1922, also gave a negative result, and the Wassermann test was negative.

Spleen.

This organ was markedly enlarged; it was placed at once in Kniserling and no cultures were made. After fixation it weighed 1,276 grams and measured 18.5 by 14.5 by 8 cm. There was distinct alteration in shape, being more rounded than normally. There were no adhesions, but the capsule was thickened and showed numerous small round localized patches of fibrous thickening. On removal the organ was fairly firm and elastic. There were no infarcts. On section the pulp was fairly uniform in appearance, being greyish pink in colour. The Malpighian bodies could be seen but were not prominent. They seemed to be reduced in number and varied in size. In or near some of them were dark red and yellow points, apparently indicating haemorrhages of varying age. Towards the hilus were two small glands about the size of peas. On microscopical examination they appeared to be haemolymph glands; they may, however, be lymph glands.

MORBID HISTOLOGY.

Pieces of the spleen and the lymph glands were fixed in formal and stained with haematein-eosin, Van Gieson, methylene blue-eosin, Leishman, Gram's stain, carbol thionin, Lovaditi for spirochaetes and also for haemosiderin.

Spleen.

The capsule shows no obvious thickening, and no infiltration with cells. The trabeculae appear to be slightly thickened by rather hyaline fibrous tissue and are infiltrated with eosinophiles in variable numbers. In some trabeculae there is a considerable quantity of haemosiderin both free and within connective tissue cells and especially in the adventitial walls of the vessels. Comparatively few of the Malpighian bodies are of lymphoid structure. Such of these as are present are small with irregular outline and composed of lymphoid cells and no germinal centres. The arteriole shows hyaline thickening. Scattered eosinophiles are present in these nodules, more especially at the periphery; no haemosiderin is found. The majority, however, show definite fibrosis of variable degree and disappearance of the lymphoid tissue. In the more advanced stages the bodies are converted into a small, round, dense nodule of hyaline fibrous tissue. Practically no lymphoid cells are present; connective tissue cells are scanty; but a small number of eosinophiles are present in the interstices of the fibrous tissue. Where the process is less advanced the individual bundles of fibrous tissue, concentric in arrangement are seen, and connective tissue cells are more numerous. In the interstices are deposits of intra- and extra-vascular haemosiderin and a few sectors at the periphery of the nodule, forming a definite nest of cells. Some of these are situated a little distance from the fibrous nodules, with which they appear to have no connexion, suggesting that they may be foci of compensatory lymphoid regeneration. Others appear to be definitely a residual portion of lymphoid tissue of the main body. In a few of the cellular Malpighian bodies a large area of the lymphoid tissue appears to be replaced by eosinophiles, both leucocytes and myelocytes, while in the surviving portion numerous eosinophiles are scattered. In relation to some of the trabeculae veins of considerable size are seen crowded with leucocytes, mostly eosinophiles.

The pulp is highly and uniformly cellular and filled with nucleated cells. There is no evident thickening of the reticulum. The sinusoids are well seen and are filled with nucleated cells; there is no obvious thickening of the walls, and while the endothelial cells are seen they are not unduly prominent. In several places there appear to be fairly recent haemorrhages into the pulp, and some of these are in the vicinity of a trabecula or fibrosed Malpighian body. The red cells appear very pale. The whole pulp is filled with cells, of which by far the greater number are eosinophilic cells. The sinusoids, too, contain a great number of these elements, and in many cases to the exclusion of practically all other cells. Eosinophiles are not confined to these places, but also infiltrate the trabeculae, where not infrequently they become elongated or flattened out in the interstices of the connective tissue fibres. They are also seen in similar fashion in the fibrosed Malpighian bodies. In the cellular Malpighian bodies they are found scattered between the lymphoid cells, especially at the periphery. As previously mentioned in one or two instances, they occur in large numbers at the periphery and seem to be replacing the lymphoid cells; nevertheless they are frequently absent from the central area of the Malpighian body.

Beneath the capsule are continuous lines of quite recent haemorrhage in which the red cells are of good colour. These haemorrhages are probably the result of the operation. In both the pulp and sinusoids the predominant cells are eosinophilic leucocytes and myelocytes, of which the former are more numerous. The eosinophilic myelocytes vary greatly in size; many are large cells with a large round vesicular nucleus; others are smaller and have a dark round nucleus. The eosinophilic leucocytes are similar to those observed in the blood; the majority have either

a two-lobed or three-lobed nucleus, while cells with four and five lobes in the nucleus occur in smaller numbers. Simpler forms in which the nucleus is merely indented are also seen. Eosinophilic cells were often seen in the process of passing through the wall of the sinuses, but the direction of their progress could not be absolutely determined. After prolonged search a very few examples of what appeared to be a mitotic figure in the nucleus of an eosinophilic myelocyte in the pulp were found, but these were the only indications of proliferation of eosinophilic cells observed in the organ. There was, however, evidence of disintegration and destruction of the eosinophilic cells as shown by nuclear karyolysis and disappearance of the granules, and examples of phagocytosis of these cells by mononuclear cells of the pulp and by endothelial cells lining the sinuses were observed. Various stages in the process of phagocytosis could be traced from the inclusion of a comparatively normal cell to the presence of nuclear debris and residual oxyphile granules. The changes concerned both the myelocytes and leucocytes, and were more conspicuous in the pulp than in the sinuses.

In addition, however, to the evidence there was also observed to be a definite part of the eosinophilic myelocytes a billic leucocytes. In and around the splenic trabeculae, where haemosiderin was abundant, there were found oxyphile cells containing several granules of this pigment within their substance, but these cells were not as active in this respect as the mononuclear cells of the pulp and endothelial cells of the sinuses. Where haemorrhages were present, and to a lesser degree in other parts, it was found that some of the eosinophilic leucocytes had ingested red blood cells and there were appearances which indicated that the included red cell underwent digestion. Apart from the great accumulation of eosinophilic cells in the substance of the organ there is little to record concerning the other cellular elements. Red blood cells were distinctly scanty except in the areas of haemorrhage; they were deficient in colour and tended to be clefted, and though an occasional nucleated form was observed there was nothing to suggest an erythroblastic reaction. Polymorph leucocytes occurred in small numbers, but no neutrophilic myelocytes were seen. Mononuclear cells were scattered in the sinuses and pulp and were actively phagocytic towards red cells, haemosiderin, and oxyphile cells. An occasional giant cell with multilobulated nucleus was observed in the pulp and resembled the myelophaques of the bone marrow. In sections stained by Gram and carbol thionin no organisms were detected, and Levaditi's method gave a negative result for spirochaetes.

Haemolymph Glands.

Both of these showed a similar structure. The lymphoid tissue was well developed. The follicles, which showed to germinal centres, were thick and cellular, and there was no evidence of atrophy or fibrosis. Eosinophilic cells—both leucocytes and myelocytes—were scattered irregularly in the interstices of the follicles, and more especially in the lymph cords, where they were abundant in the vicinity of the sinuses. They were very scanty in the centres of the dense follicles at the periphery of the glands. In a few places there were appearances analogous to those seen in the spleen—namely, large areas where the lymphoid tissue had been replaced by a dense accumulation of eosinophilic cells, the majority of which were leucocytes. The sinuses contained red blood cells, phagocytic mononuclears, and numerous eosinophiles. The latter presented the appearances already described in the spleen. Frequently oxyphile cells were seen passing through the wall of the sinuses, but here too it was impossible to determine the direction of progress. Eosinophilic myelocytes—especially the larger forms—were more numerous in the interstices of the lymphoid tissue than in the sinuses, but no histological evidence was obtained that these cells arose in the former situation. The only mitotic figure seen occurred in an eosinophilic myelocyte lying free in a sinus. Similar changes were noted as regards destruction of eosinophiles as were found in the spleen; in the lymphoid tissue, and especially in the sinuses; phagocytosis of these cells by mononuclear cells was observed.

Eosinophiles were present in both the sinuses and lymph cords, which were phagocytic to red blood cells, and some of them contained granules of haemosiderin. The only other feature of special note was the presence of considerable quantities of haemosiderin which occurred as intra- and extra-cellular masses throughout the follicles and cords in particular, and to a lesser extent within free phagocytes and lining endothelial cells of the sinuses. Further evidence of blood destruction was seen in the presence of numerous mononuclears in the sinuses which had ingested red cells.

Phagocytic Activity of the Eosinophiles.

The richness of this patient's blood in eosinophiles afforded a good opportunity of attempting to estimate their phagocytic power, and observations were made on two separate occasions.

For this purpose we used a culture of *Staphylococcus aureus* from a fatal case of acute infective osteitis; the same organism (twenty-four hours' culture) was used on both occasions. One volume of a standardized emulsion of this coccus with two volumes of the patient's blood was incubated at 37° C. and examined after twenty minutes. The observations were controlled by comparison with the blood of one of us. It was obvious that the eosinophiles were distinctly phagocytic towards the cocci. On each occasion the cocci were counted in 300 eosinophiles. Though a prolonged search was necessary, the number of cocci in 300 of the patient's polymorphs was also noted. In the case of the control blood the eosinophiles were so scanty that only corresponding observations on 300 polymorphs were attempted. The attached table shows the results. (Table III.)

TABLE III.—Eosinophilia.

Illustrating the phagocytic power of patient's eosinophiles as compared with his own polymorphs.

Date.	Phagocytic Index of Polymorphs.	Phagocytic Index of Eosinophiles.	Ratio of Phagocytic Power of Eosinophiles to Polymorphs.
December 16th, 1921	6.95	1.78	1:3.9
June 29th, 1922	6.85	0.72	1.95

Illustrating the phagocytic power of patient's eosinophiles as compared with control's polymorphs.

Date.	Phagocytic Index of Polymorphs.	Phagocytic Index of Eosinophiles.	Ratio of Phagocytic Power of Eosinophiles to Polymorphs.
December 16th, 1921	5.18	1.78	1:3.0
June 29th, 1922	5.45	0.72	1:7.57

These observations leave no doubt as to the very considerable phagocytic power of the patient's eosinophiles, and considering the great increase of these cells in his blood it is obvious that the total phagocytic activity of the oxyphile leucocytes is pronounced. It is also apparent that on the date of the last examination there was a very considerable depreciation of the phagocytic power of the eosinophiles. We have only made a few observations on the relative phagocytic power of the different types of eosinophilic leucocytes. The result of these preliminary observations was that while we found some phagocytic power on the part of the eosinophilic myelocytes, those with the simple indented nucleus were about twice as active, while the cells with two-, three-, and four-lobed nuclei were evidently the main phagocytes.

Observations on Charcot-Leyden Crystals.

Although the nature and significance of Charcot-Leyden crystals are still undetermined, yet there appears to be strong evidence in support of the view that they are in some way a product of eosinophilic leucocytes. The marked eosinophilia present in this patient has afforded an opportunity of inquiry along these lines.

Two volumes of blood were withdrawn, under aseptic conditions, into two tubes on two consecutive days, kept at 37° C., and examined periodically both in the fresh state and in films stained by Leishman. A volume of normal blood was used for control observation. In the first forty-eight hours no crystals were found and the oxyphile leucocytes were well preserved. On the third day an occasional eosinophilic leucocyte was observed containing a typical Charcot-Leyden crystal. All the crystals found were intracellular; some were considerably smaller than the diameter of the cell, while others were longer and showed one end projecting outside the cell boundary. The eosinophiles were still well preserved, and there was little evidence of disintegration. On the fourth day large numbers of crystals which varied greatly in length were present. Many of the small forms were intracellular, while the large ones—several times the diameter of a leucocyte—were lying free. Frequently two or more small crystals were observed within the same cell. In the stained films both extra- and intracellular crystals were coloured a faint blue by the Leishman, while a few eosinophiles were seen to contain clear colourless spaces in their cytoplasm which from their shape and size evidently represented the positions of crystals which had been dislodged from the cell. There was now more evidence of broken down leucocytes than previously, although eosinophiles of normal appearance were abundant.

Examinations made on the fifth, sixth, tenth, and fourteenth days confirmed the appearances already noted, save that on the last occasion the blood had become contaminated by bacteria. It is of interest to note that eosinophiles of practically normal appearance persisted throughout in large numbers. No crystals were found in the normal blood at any time during the observations. Throughout the series of observations it was strongly suggested that the small Charcot-Leyden crystals were the oxyphile leucocytes, and not the eosinophiles. In fresh preparations agitation and pressure failed to release the crystals until the cell had been ruptured, while the appearances already described in the stained films confirm this view. The presence of intracellular crystals did not appear to be associated with any specific alteration in the structure of the cell, the crystals being found within both well-preserved cells and ones which were obviously degenerated. As far as could be seen there was no appreciable difference in the number of crystals found on the fourth day and the fourteenth day. No evidence of crystal formation was found in the polymorph leucocytes or other cells of the blood. The crystals were a faint green tint, refractile, and had the shape of an octahedron. They were soluble in hot water, 2 per cent. acetic acid, and NaOH; insoluble in absolute alcohol, ether, xylol. They did not stain with 5 per cent. alcoholic eosin or Sudan III.

The appearances found lead us to suggest: (1) that the crystals are first formed within the substance of the eosinophilic leucocytes; (2) that the cells eventually break down and liberate the crystals, which then grow into larger formations;

(3) that there is no definite evidence that the crystals primarily arise from the oxyphile granules of disintegrated eosinophilic cells; and (4) that the conditions which lead to the formation of crystals appear suddenly about the third to fourth days. This case would appear to afford a good opportunity for further work on the lines of Liebroich's investigations on the relationship of eosinophilic granulations to the coagulation of blood.

In view of the suggestion which has been made by some writers that the yellowish tint of the lymph glands in lymphadenoma is due to the presence of eosinophilic cells, it seemed to us that the present case provided a suitable opportunity for determining the colour produced by eosinophilic leucocytes *en masse*. About 5 c.cm. of blood were obtained from a vein and allowed to coagulate. The "buffy coat" which formed showed no yellowish tint, and appeared identical in colour with a normal control coagulum, nor did any such tint develop after more than a week.

CONCLUSIONS.

It is only possible to speculate as to the real nature of this condition. Judging from the literature we have access to, it seems to be extremely rare. The only similar case which has been recorded in any detail was described by Giffen.² The case was observed in the Mayo Clinic and was described as "persistent eosinophilia with hyperleucocytosis and splenomegaly." The case presents in all its essential features such a close similarity to our own that it is impossible to come to any other conclusion than that we are dealing with a definite clinical and pathological entity. Giffen summarizes the case as follows:

"F. H., male, aged 31 years. Marked splenomegaly. Slight enlargement of superficial lymph glands. Leucocytosis 21,800 before splenectomy, with an eosinophilia of 73.6 per cent. Splenectomy July 15th, 1914. Weight of spleen 2,110 grams. Macroscopic appearances of spleen similar to that of myelogenous leukaemia. Rapid increase of leucocyte count to 97,203, and later to 211,000; eosinophilia from 79 to 99.7 per cent. Good general condition for period of four years following splenectomy. Death January 19th, 1919, of encephalitis. Enormous numbers of eosinophils in all haemopoietic organs. Eosinophils in lymph glands, spleen, and bone marrow. Obliterative pericarditis and fibrous peritonitis."

[Note.—There is probably a clerical error in the above account. The description of the spleen, which had been removed four and a half years previously, is included in the *post-mortem* record.]

One gathers from the account of the case that the patient was first seen in March, 1913, and at that time the total white cell count was 15,400, with 66.3 per cent. of eosinophiles; the liver and spleen were enlarged. The known duration of the disease was six years, while the clinical history suggested one and a half years prior to this. Splenectomy was performed in 1914. It is stated that the eosinophiles in the spleen at this time were much less numerous than in the lymph glands examined at the section four and a half years later.

In reviewing the literature Giffen states that he has only found one similar case, that of Stillman.³ Stillman describes his case only very briefly under the title of "Mycoid leukaemia with predominance of eosinophilic cells."

The patient, a native of Spain, was observed in the New York Hospital in 1911. He was a man 27 years of age, and was apparently syphilitic. He was anaemic, and showed some general enlargement of lymph glands. There was enlargement of liver and spleen. The urine constantly showed a trace of albumin and a few casts. There was no evidence of a parasitic invasion of the alimentary canal.

The leucocyte count varied from 118,000 to 165,000 per c.mm., and eosinophiles from 85.8 to 91 per cent. A differential count at a time when the number of leucocytes was 165,000 gave the following results:

Polymorphs	3.8 per cent.
Eosinophile polymorphs	69.8 "
Eosinophile metamyelocytes	19.4 "
Eosinophile myelocytes	1.8 "
Mesoblasts	0.2 "
Transitionals	0.8 "
Lymphocytes	4.2 "

The eosinophiles were rather larger than those usually seen in the blood and the granules were rather smaller. Normoblasts were present in a ratio of 2 per 100 leucocytes.

The patient was lost sight of and the subsequent history is unknown.

Assuming that the "metamyelocytes" in this account were only varieties of the eosinophiles, and that the true myelocytes were only 1.8 per cent. as stated, the case can hardly be

described as an ordinary leukaemia, and would apparently find a place in the special group we are now considering.

It is indeed remarkable that, considering the very definite blood changes in this condition, we have found such a small number of recorded cases. The condition could hardly be missed in an ordinary full examination of the blood, and even assuming that other cases have been recorded since 1919 the condition must be regarded as very rare indeed.

We have heard of another case, under the care of Dr. Edwin Matthew, Edinburgh, in 1909, which has some points of resemblance to ours. The patient, a girl of 12, was under observation in Leith Hospital for about six weeks. She was admitted for digestive trouble, but a marked eosinophilia was found, the leucocyte count from 12,000 to 15,000, and repeated differential counts showed an eosinophilia percentage of 85. Parasitic infection was excluded. There was no splenomegaly. This may well have been an early stage of the condition we are describing, and the subsequent history would have been most interesting. Unfortunately the family left the district soon after the patient's discharge from hospital, and nothing further has been heard of the case. Aubertin and Giroux⁴ report a case which resembles those described by Giffen and Stillman.

The patient was under observation for four years suffering from dyspnoea and cyanosis. A diagnosis of primary sclerosis of the pulmonary artery with consecutive cardiac insufficiency was made. The spleen was slightly enlarged. There was a marked permanent eosinophilia; the total white cell count averaged about 10,000 per cubic millimetre, varying between 6,900 and 26,000. The percentage of eosinophiles remained constantly between 65 and 70.

Splenectomy was excluded; the Wassermann reaction was negative. The patient died of cardiac failure. The clinical diagnosis of sclerosis of the pulmonary artery but, unfortunately, no study of the blood-forming organs was made.

The authors consider that the cause of the eosinophilia in this case was anaemia, and point out that Giffen's case also was associated with serious cardiac disease. So far as the clinical observations on Stillman's case go, it may be pointed out that there was no evidence of cardiac disease. They discuss the arguments for and against the condition being a leukaemia, but appear to negative the idea. It is doubtful if this case can be considered as belonging to the group we are now describing—the total leucocyte count never exceeded 26,000 and the blood condition did certainly not progress as in Giffen's case and our own. The subsequent history of cases resembling that of Aubertin and Giroux may be very interesting, for we have no real evidence in our own case nor in those of Giffen and Stillman of how long the disease had been in existence when the patient first came under observation. Apart from splenic enlargement or from some complication, it is difficult to imagine how attention would be directed to the blood, and without a blood examination the condition could not be recognized.

Of more importance, however, in our present discussion is a case of "splenomegaly with polymorphonuclear neutrophil hyperleucocytosis" described by Tuohy.⁵

The case was that of a female, aged 58. She had acute arthritis at 16, but there was nothing else of moment in her family or past history till she developed uterine prolapse at the age of 40. Her present illness started with pain in her side, and on examination she was found to have an enlarged spleen. On physical examination nothing was discovered beyond a pessary, which she had worn for fourteen years. There was local irritation as a result. This soon subsided. A blood examination showed a leucocytosis of 65,000. A differential count showed 99 per cent. polymorphs. The discomfort and abdominal distress suggested the advisability of splenectomy. This was carried out successfully, with an uninterrupted recovery. The leucocyte count rose, however, in three days to 240,000, but the leucocytosis subsided in about a month to 45,000. For over a year she was able to carry on her household duties, but some seventeen months after the splenectomy she succumbed to an acute pneumonia after a week's illness. Unfortunately no details of the blood condition after she left hospital in 1917 are available, and an autopsy was not permitted.

In discussing the case, Tuohy draws a parallel between his case and that of Giffen, and regards them both as examples of a condition where there must be a hyperplasia of individual elements in the bone marrow—namely, the neutrophilic myelocytes and eosinophilic myelocytes respectively. He regards the condition as a hyperleucocytosis rather than a leukaemia. He draws a distinction depending on whether the myeloblastic reaction is lawful and benign, or, as he puts it, Bolshevistic and malignant. We have heard of another case of hyperleucocytosis, where basophilic leucocytes were the predominant cells. We have no details, however, and cannot vouch for the observation. Gluzinski and Reichenstein⁶

report a case of myeloma in which a large proportion of 39,640 leucocytes per cubic millimetre were of the plasma cell type, and speak of a plasma cell leukaemia.

As will be stated presently, we are rather inclined to regard our case as one of leukaemia of a special type, and in view of the above observations it may be necessary to widen our conception of leukaemia and be prepared to find isolated examples of benign leukaemias affecting neutrophilic, eosinophilic, and basophilic elements.

As we have said, one can only speculate as to the cause and nature of this condition. It seems possible, however, to arrive at some general conclusions. Giffon² was inclined to regard the condition as an instance of an "eosinophilic leucocytosis, the blood picture of which was remarkably altered by splenectomy," rather than a true leukaemic condition, though he is not prepared to exclude altogether the latter suggestion. He further states that the condition "may be indicative of some special function of the spleen with respect to eosinophilic cells or with respect to the toxins which eosinophilic cells are capable of absorbing."

In the first place, we cannot see that the splenectomy has seriously influenced the condition or modified the blood picture to any extent in either his case or our own. The splenectomy has only been followed by a more marked blood condition, the essential qualities of which have been otherwise unchanged. It may be pointed out also that Stillman's case, which appears to be of the same nature, ran a similar course in the absence of splenectomy.

An attempt to draw a distinction between an eosinophilic leucocytosis in response to some definite toxic influence, and a true leukaemic condition would appear to us to be extremely difficult in the present state of our knowledge, but it is very difficult to bring this small group of cases into line with cases of eosinophilia due to known toxic influence. The degree of eosinophilia here, both relative and absolute, its persistence, and its increasing intensity do not seem to us to fit in with what we know of eosinophilia due to a definite toxin, say of some animal parasite. We have excluded so far as we can in our case the ordinary established causes of eosinophilia, with the exception of trichinosis. Giffon, in his case, did this during life by removal of a portion of muscle, and the post-mortem examination also proved negative in this respect.

We are rather inclined to the view that we have here a condition of the bone marrow primarily affecting the eosinophilic elements; a condition therefore more allied to a true leukaemia but of a most unusual type. The essential source of the eosinophiles we regard as the bone marrow. We do not find any active formation of eosinophiles in either the spleen or the haemolymph glands examined. The intense infiltration of these organs with eosinophilic cells we regard as merely the result of filtration of these cells from the blood. Evidence of actual mitotic division of eosinophilic myelocytes, though present, is extremely slight. It appears to us much more probable that the few dividing eosinophiles observed came from the blood and were not formed locally. On the other hand, evidence of destruction of the eosinophiles by a phagocytic action on the part of the other cells in the spleen and lymph glands seems perfectly clear in our case. The gradual rise in the number of the eosinophiles may be due to the persistence of the original cause whatever it may be, but this may be accentuated by the loss of so much phagocytic tissue following removal of the spleen, or by the gradual loss of the phagocytic action of the endothelial or other cells through the slower retrogressive change in the spleen where not excised—for example, in Stillman's case—and in the lymph glands. As we have said, we have entirely failed to demonstrate any infective agent in this case, and, though this does not enable us to deny its existence, it seems fully more reasonable to explain the condition by some altered habit of the cell such as occurs in true neoplasia and not necessarily dependent on some external agent or influence.

It is to be feared that there is less doubt as to the course and termination of the disease. So far there is no evidence that this patient's blood is inferior to that of a healthy person in phagocytic and protective power. We have inquired particularly in this direction and, so far as we can ascertain, this patient, who by the nature of his work often suffers from cuts and abrasions on his hands, differs in no way from a normal person in the direction of a greater liability to local infections or in the healing power of his tissues. Not only, however, must there be a great and increasing strain on the bone marrow in this eosinophilic hyperplasia, but the other

infiltration with eosinophiles, and we must expect a steady deterioration of the marrow as a whole with a consequent increasing risk of secondary infection. A terminal infection will still further complicate the problem, and in the event of a fatal issue we can hardly expect much light on the original and essential cause of the disease.

The result of splenectomy in this case seems worthy of some consideration. As in Giffon's case, removal of the spleen has resulted for the time being at least in great improvement in the patient's physical condition, all the more remarkable when one notes that during this time the eosinophilia was becoming more marked. Splenectomy is the fashionable operation of the day. In many conditions no doubt—for example, certain types of splenic anaemia and alcoholic jaundice—splenectomy may result in an apparent cure. We have seen examples of this, and apparently in some localized infections of the spleen—for example, syphilitic and tuberculous—a favourable result may also be obtained by splenectomy. The operation has, however, been frequently performed in recent years in conditions where at best only a temporary improvement can be anticipated, though a study of the after-results in these cases may add to our knowledge of the obscure problem of the functions of the spleen. Time does not permit us to even refer to the many theories, or rather vague hypotheses, which have been advanced. A glance at the cursory way in which the subject is dealt with in even our standard works on physiology will convince us of our ignorance in this direction. Though the operation has often been performed in diseases in which cure cannot be looked for by this treatment, there seems no doubt that an apparent temporary improvement often occurs, and there is increasing evidence to show that the spleen may have an important though indirect influence on blood formation in addition to the well-established destructive action on effete cells. Recent experimental work by Eddy³ points in this direction. It may well be that the explanation of some obscure blood conditions will be found in a perversion of this function.

In our present case the improvement in the physical condition following splenectomy, associated as it was with an increase in the eosinophilia, appears to us to be evidence in favour of the view that no active formation of eosinophiles was occurring in the spleen. The rise in the eosinophile count is more easily explained by the loss in amount of the phagocytic tissue of the spleen. It must be admitted that if this were so one would have expected that for a time at least after the removal of the spleen the blood counts would have shown a higher proportion of older eosinophile cells if, as seems reasonable, an increasing lobulation of the nucleus points to an older type of cell. As has been pointed out, however, the proportions of the different types of eosinophiles has remained remarkably constant. It must be remembered, of course, that in this case the spleen was removed after it had undergone a considerable amount of structural change, and judging from the alteration in the haemolymph glands and from the evidence of their increased phagocytic action, some of the functions of the spleen had evidently been already taken on by the glands for some considerable time. The alteration produced by the splenectomy was therefore not so sudden as may appear at first glance and the preservation of the different proportions of the eosinophiles may be only further evidence of the delicately regulated mechanism for dealing with effete blood cells, both red and white.

It is, of course, clear that patients may survive a splenectomy without apparent harm being done to the general health. Splenectomies necessitated by traumatic rupture prove this. At the same time one is left with a certain uneasy feeling that we have no clear conception of what actually occurs when the spleen is removed. The size of the spleen, its anatomical relationship (especially its relation to the portal circulation), its possible relation to gastric function, all seem to make it very improbable that all of its function can be completely compensated for by a hyperplasia of lymphoid tissue elsewhere in the body. Further information would seem to be urgently required as to the later histories of cases of splenectomy. The post-mortem examination of cases which survive the operation for some years might yield some information of importance, and the clinical histories of such cases should be even more carefully studied than has been the case in the past, with special reference to the question of increased liability to infection or diminished capacity to deal with it when it does occur. In such a condition as the case now recorded, of course, a liability to secondary infection might almost be looked for as a direct result of the disease and the consequent strain on the bone marrow.

FIG. 1.—Blood film showing the degree of leucocytosis; practically all the cells present are eosinophiles. The variation in the size of the white cells and in the number of the granules is well seen.

FIG. 2.—Section of spleen showing the characteristic eosinophilic vacuoles in the cells, which are well seen.

FIG. 3.—Section of spleen showing replacement of a large area of a Malpighian body by eosinophiles. (The larger cells towards one side of the body.)

FIG. 4.—Section of spleen, showing in the centre of the field an atrophied Malpighian body with replacement fibrosis. The lymphoid nodule in the vicinity may represent the remains of the Malpighian body or an attempt at compensatory lymphoid hyperplasia.

FIG. 5.—Section of spleen, showing a sinus crowded with eosinophiles, which are also infiltrating the surrounding pulp.

FIG. 6.—Section of haemolymph gland, showing a sinus containing red cells, and lymphoid tissue.

TILLEY: PAPER FASTENER REMOVED BY DIRECT PERORAL BRONCHOSCOPY.

Dr. Salmund's skiagram of patient's chest, showing the paper fastener in the distal portion of the left bronchus.

SOUTHAM AND WILSON: CANCER OF SCROTUM.

Photograph showing the characteristic attitude adopted by the mule-spinner when leaning over the machine to piece the broken threads.

FIG. 1. - Plantar aspect of squamous epithelioma and hyperkeratosis, following arsenical administration.

FIG. 2. - Keratosis plantaris (arsenical).

FIG. 3. - Keratosis palmaris (arsenical).

FIG. 4. - Microphotograph (1/3 Zeiss objective). Squamous-celled epithelioma with cell nests, and neoplastic endolymphatic extension, etc.

FIG. 5. - As Fig. 4 (1/7 Zeiss objective). Note cell nest.

What may actually happen after excision of the spleen is well illustrated by a case published by McAdam Eccles and Freer.⁶ In this case splenectomy was performed for traumatic rupture in 1910. In 1920 the patient was again operated on for a ventral hernia, the result of the first operation, and on this occasion what appeared to be a spleen normal in every respect was observed in the course of the operation. The evidence of a new formation of a spleen seems perfectly clear from the facts presented. The authors regard this as having resulted from a hypertrophied spleniculus which may well have escaped notice at the first operation. This remarkable occurrence seems to indicate clearly the advisability of leaving behind any such spleniculus which may be observed in the course of an operation for splenectomy necessitated by trauma.

Further Report.

Since this paper was read we have had another opportunity of seeing the patient and making a further blood examination with the following result. The details of this blood examination appear at the end of Tables I and II, and are marked with an asterisk.

The patient reported, by request, at the Royal Victoria Infirmary on September 28th, 1922. He says that he feels perfectly well, appetite is good, and he has no pains anywhere. Is still constantly

at work, which is obviously strenuous. He looks rather fine drawn; his appearance suggests some anaemia. His weight is 9 st. 3 lb., representing an increase of 6 lb. since the end of June. The superficial glands referred to previously are still palpable, but if anything are smaller than previously. There is no enlargement of liver; there is no dullness in splenic region.

Urine.—Reaction, acid; albumin, nil; sugar, nil. Deposit: No casts or cells; abundant deposit of amorphous urates.

Faeces.—No parasites or their ova found.

Blood.—Red blood corpuscles, 4,087,000 per c.mm.; white blood corpuscles, 138,250 per c.mm.; haemoglobin, 58 per cent.; colour index, 0.71. The appearances of the films show no essential difference from that previously seen. In a differential count of 300 leucocytes the eosinophiles account for 79.3 per cent. Coagulation time was 4 minutes, against a normal control time of 5. There appeared to be again some diminution in the blood platelets.

The result of this last examination gives further proof of the progressive nature of the disease so far as the blood condition is concerned. The patient remains under observation and the progress of the case will be recorded at a later date.

CANCER OF THE SCROTUM:

THE ETIOLOGY, CLINICAL FEATURES, AND TREATMENT OF THE DISEASE.

BY

A. H. SOUTHAM, M.A., M.Ch.Oxon., F.R.C.S.Eng.,

AND

S. R. WILSON, M.B., M.Sc.Vict., F.R.C.S.Edin.,

MANCHESTER ROYAL INFIRMARY.

[With Special Plate.]

EPITHELIOMA of the scrotum has hitherto been generally regarded as a disease which occurs chiefly among chimney-sweeps. It is practically the only type of malignant disease met with in the scrotum, and has received the distinctive name of "chimney-sweeps' cancer" for that reason.

The earliest accounts of sweeps' cancer appear to have been written by Mr. Potts and Mr. Henry Earle¹ in 1832. Sir James Paget in his *Surgical Pathology*, published in 1853, states that this disease is fairly common in England in large towns, but in other countries is rarely seen. The most interesting communication on this subject was Sir Henry Butlin's² three lectures at the Royal College of Surgeons in 1892 on "Cancer of the scrotum in chimney-sweeps and others." He found the disease was seldom seen except in Great Britain, and that it occurred chiefly among sweeps. In 48 collected cases 34 were chimney-sweeps, the remainder being in other employments, showing an enormous preponderance among the former class. He came to the conclusion that it was due to the irritant action of soot on the parts, and he further pointed out that it did not occur where wood, peat, and charcoal were burnt, nor did coal-miners suffer from this condition.

In the report of the Departmental Committee on Compensation for Industrial Diseases (1907) it is stated that the mortality for cancer among chimney sweeps is twice that among occupied males generally. For the three years 1900-2 the comparative mortality figure for cancer among sweeps between the ages of 26 and 65 was 133, as compared with 63 among other occupied males of the same age.

In 1916, in *Diseases of Occupation*, Sir Thomas Oliver states that scrotal cancer is prevalent in chimney-sweeps and he attributes this to some peculiar chemical change when coal is burnt, whereby the soot formed has specially irritating characters on the skin. Reference to any of the leading surgical textbooks gives a general impression that epithelioma scroti is relatively common in chimney-sweeps, whilst Thomson Walker³ writes: "Epithelioma of the scrotum is more frequent in chimney-sweeps than in other males, and has thus received the name 'chimney-sweeps' cancer." It has more recently been established that prolonged exposure to tar and its products tends to produce epitheliomatous ulceration of the skin. In January, 1920, the Home Secretary made epitheliomatous ulceration due to tar, paraffin, and

mineral oil a notifiable industrial disease. This form of ulceration is liable to occur on the scrotum. In view of these statements we were led to make further inquiry into the incidence of this disease, and proceeded to collect and investigate all the cases of cancer of the scrotum admitted to the Manchester Royal Infirmary from the years 1902 to 1922. During this period 141 cases of this nature attended the hospital, and out of this total there was only one single case whose occupation was that of chimney-sweep.

Further inquiry has enabled us to throw additional light on the etiology of this condition—a matter of considerable importance, both as regards the causation of cancer of the scrotum and the preventive methods that may be adopted to reduce the occurrence of the disease.

ETIOLOGY.

During the period under review 141 cases of cancer of the scrotum attended the Royal Infirmary—an average of seven cases each year. The average age of these patients was 51 years when seen at the hospital. The following is an analysis of their occupations, and is of considerable interest:

Mule spinners	69
Tar and paraffin workers	22
Sweeps	1
Various occupations*	38
Occupations not stated	11

141

These figures show that epithelioma of the scrotum was largely associated with two occupations in South Lancashire—cotton-spinning and workers in tar and paraffin. Spinning being one of the chief industries in the district we were led to continue our investigations and endeavour to ascertain what connexion, if any, existed between this occupation and the disease under consideration. It would appear that there is some factor in the trades of sweeps, tar workers, and cotton spinners whereby the skin of the scrotum is liable to the occurrence of cancer.

1. Chimney-sweeps.

Sufficient has already been written under this heading to show that in the past soot was considered an important factor in the production of cancer. In our series of 141 cases, however, there was only a single chimney-sweep. It may be assumed that with improved methods of chimney-sweeping, and greater attention to cleanliness on the part of the workers, chimney-sweeps' cancer is on the decline, in Lancashire at any rate.

2. Tar and Paraffin Workers.

The relation of tar and cancer was first recognized by Professor Volkmann⁴ in 1875. He published a paper on "Tar,

* No definite etiological factor was discoverable in this group, many being classified as labourers, and no details of their employment given. In two cases a truss had been worn on the side of the growth for a number of years.

paraffin, and soot cancer," and described three cases where epithelioma of the scrotum occurred in workers in these substances. In 1876 Dr. Joseph Bell⁶ independently described two cases of carcinoma of the scrotum under the title "Paraffin epithelioma of the scrotum." Tar and paraffin are now regarded as active agents in the causation of cancer, due to their irritant action on the tissues.

Recent research has shown that cancer can be produced in animals. Bloch and Dreifuss⁷ produced tumours in mice by painting their backs with coal tar in 160 days, and also found metastatic deposits in their lungs. As already stated the Home Office has made ulceration due to tar and paraffin a notifiable industrial disease. Forty-five cases of this nature were notified in 1920. One may therefore conclude that from experimental and clinical evidence it is possible by the repeated application of these substances to produce cancer of the skin. In man there appears to be a correlation between these substances and cancer of the scrotum, just as smoking has long been considered to predispose to cancer of the mouth.

3. Cotton-spinners.

In the present investigation we propose to discuss another occupation which accounted for the largest number of cases in the series. Cotton-spinning has not hitherto been considered an industry of importance in this respect. In the present series 53 per cent. of the cases whose employment was ascertainable were engaged as mule-spinners. To further investigate this matter we have visited a cotton mill in the Pendleton district of Manchester, and examined the men and the conditions under which this class of work is carried out.

Mule-spinning is undertaken entirely by men, women not being employed in this process of the cotton trade. Many of the workers have spent the greater part of their lives in the mill—often upwards of thirty years. The fact that in so large a proportion of the cases the growth has been found to be situated on the anterior aspect of the left side of the scrotum led us to consider if there was any special factor in the occupation of mule-spinning to account for that position.

For the information of those who are not familiar with the mule-spinning process it may be said that the special feature is a type of movable rack, known as the carriage, which carries the receiving spindles for the yarn that is being spun from the cotton. This carriage varies in length, and may be as long as ten to twenty yards, and carry 1,000 or 1,500 spindles. The carriage is worked by machinery, moving continually to and fro, the stretch being usually sixty-four inches. This movement occurs three times in the minute. On the carriage, about three feet from the ground, is a steel bar extending the length of the machine. This bar is found to be moist with the lubricating oil thrown out by the spindles as they revolve; the oil further contaminates the clothes of the spinner, for careful oiling of the spindles is necessary. As the carriage moves to and fro the cotton threads which are being spun into yarn may break from time to time. It is the duty of the mule-spinner, or minder, to follow the mule and attend the spindles and piece the threads when they break. This necessitates him constantly leaning over the carriage, which brings his thighs and scrotum into contact with the oil-covered bar and its accessories. In watching the spinner at work one is struck by the fact that when leaning over to piece the threads he almost invariably stands on the left leg, the right leg being thrown out behind to act as a counterbalance as he bends forwards. He meanwhile pieces the threads with his left hand. This results in the left groin and left side of the scrotum continually coming into contact with the bar of the carriage. The workers state that they are accustomed to adopt this attitude from their earliest days. (See Special Plate.)

The atmosphere in the mill where the work is carried on is extremely warm and humid and the men perspire freely. Under these conditions the mule-spinner wears the minimum amount of clothing. He works in a shirt and a pair of washable linen trousers and has bare feet. These trousers are said to be washed each week, and an inspection at the end of that period shows a well-marked oil zone, six to eight inches in depth, across the body at the level of the upper part of the thighs and lower abdomen. This oil penetrates the trousers and the lower border of the shirt also becomes soaked with it. The skin in this region is therefore constantly exposed to contamination and irritation from the oil, and itching and scratching of the parts is found to be by no means uncommon. The oil in general use is said to be a mineral oil of the paraffin series.

The striking feature which becomes evident is the liability of the scrotum to be affected with cancer in certain occupations. Epithelioma of the scrotum is a disease of adult life and mature adult age, and in the majority of cases it appears to arise as the result of the specific action of some substance on the skin of the scrotum. This substance may be met with in soot, tar, and oil, and probably acts as a local irritant, and so prepares the tissues whereby cancerous growth may take place. In the case of the mule-spinner it would appear that the scrotum is liable to irritation, a point further emphasized by the fact that in most of the cases the ulcer was found in the same situation—namely, the anterior aspect of the left side of the scrotum. The actual cause of the irritation seems to depend on two factors:

1. *Mechanical*.—The result of friction of the parts with the clothing and the repeated traumatism of the body against the machine over which the spinner works. In addition there is the contamination of the clothes with dirt and sweat unless particular attention is paid to cleanliness.

2. *Contact with Oil*.—As regards the oil factor, the continual soiling of the clothes with oil and the knowledge that in other forms of cancer tar and paraffin are recognized as direct etiological agents—a view which has received considerable support from experimental work on animals—suggests that the oil, which has a highly irritant action on the tissues of the skin, may be of considerable importance.

These factors may lead to the production of a wart, the usual form in which the growth is found to originate, and in those above middle age, and in individuals susceptible to its effect, takes on the characteristics of epithelioma. It is our intention to further investigate at the Manchester University the cancer-inducing properties, if any, of the various lubricating oils in common use in cotton mills.

CLINICAL FEATURES.

From anatomical considerations it might be expected that the scrotum would be peculiarly liable to cancer. Its position, its exposure to continual irritation, its roughness, and the presence of hairs all predispose to the accumulation of dirt and septic matter and lead to irritation of the parts.

Whilst in general features epithelioma of the scrotum closely resembles other forms of surface cancer, particularly epithelioma of the lip, yet it exhibits certain differences from the typical chimney-sweeps' cancer as described by Butlin. Multiple warts are not the rule. The growth, in our experience, is nearly always solitary and most commonly situated low down on the anterior aspect of the scrotum on the left side (84 per cent. of cases). In 10 per cent. it was localized to the right side, and in 6 per cent. it commenced in the mid-line of the scrotum.

The earliest manifestation is almost invariably a wart, yet even this cannot be regarded as of an innocuous nature, for local removal of this wart is frequently followed by the appearance of malignant deposits in the groin some twelve to eighteen months later. This no doubt explains the so-called cases of primary epithelioma of the inguinal glands described by Butlin and others. The patient has forgotten all about the wart, and the resulting scar is so small and difficult to recognize in the rugose scrotum, or the growth has been missed owing to imperfect observation. It would appear that there is no definite pre-cancerous stage but that the wart is malignant from the beginning. The warty stage persists for some four to six months, the tumour varying in size from sixpence to half a crown, then ulceration occurs, and the typical epitheliomatous ulcer develops. The rate of growth varies, but on the average from the time of onset to the time the patient came to hospital for treatment was twelve months.

Local spread is not of a very rapid character; in 6 cases of the series the testicle was involved by the growth, whilst only 3 did it spread on to the penis. On the other hand, secondary involvement of the inguinal glands is extremely common, the early enlargement being due to inflammatory changes. Later they become the seat of definite malignant deposits.

Recurrence of the disease in the groin is very common; this is probably owing to the fact that in many cases a radical operation had not been performed, the glands having simply been locally excised, and only in the more recent cases has the operation performed been of sufficient extent to remove all the infected tissues.

As regards the last stages of the disease the most conspicuous feature is the breaking down of the malignant

glands in the groin, death in some cases being due to haemorrhage from the external iliac or femoral vessels; in other cases death is due to septic absorption and exhaustion. In only one case of the series was the peritonium involved; in this case, as the bowel also was affected, it was necessary to do a colostomy. There appears to be little tendency to the formation of metastases in distant organs.

TREATMENT.

The operative treatment of cancer of the scrotum usually receives but brief discussion in the surgical textbooks. The technique of the operation is of considerable importance, for when this is radically performed there appears a good prospect of a successful result. Glandular metastasis occurs fairly early, and it is only by a complete dissection that all the infected tissues in the inguinal regions can be satisfactorily removed. The importance of the lymphatics draining from the scrotum was emphasized by Morley¹ in 1911, and an attempt made to place the operation on a sound anatomical basis. The technique here described is largely based on the result of that work.

The radical operation consists in removal of the growth in the scrotum together with a wide margin of healthy tissue around it, and the complete excision of the glands and surrounding fatty tissue in both groins. The operation is in many respects similar in type to the radical amputation for carcinoma of the breast and merits equal attention. The scrotal growth is excised with at least one inch of healthy skin surrounding the base of the tumour; the whole thickness of skin and dartos should be taken away. The lymphatic glands must always be removed from both groins. There is free anastomosis between the superficial lymphatic network of opposite sides, and if the growth approaches the median raphe bilateral infection may be present at an early date.

The operation differs in one respect from the radical amputation of the breast in that the so-called block dissection, where the entire glandular area and the lymphatic trunks between the tumour and the glands are cleared away, does not appear to be necessary. It is found sufficient to remove the scrotal growth and the tissues of the groin through separate incisions. This is comparable to the operation performed for malignant disease of the tongue, where it is not usually considered necessary to remove the tissues between the growth and the glands. The best incision for removal of the glands is one parallel to and below Poupart's ligament, extending from the anterior superior spine to the spine of the pubes; from the centre of this a vertical incision is carried a short distance down the thigh. This incision allows good exposure of the infected tissues and their easy removal. The earliest glands that may be infected, when the growth is on the anterior aspect of the scrotum, lie just internal to the anterior spine, so the dissection must be carried out to this point. All the glands and fatty tissue in Scarpa's triangle should be excised and the vessels left stripped clean, whilst the upper part of the saphenous vein may be removed with advantage.

CONCLUSIONS.

1. Epithelioma of the scrotum is rare among chimney-sweeps in South Lancashire.
2. In this district the disease is most frequently met with in mule-spinners ("mule-spinners' disease").
3. The growth is usually situated on the anterior aspect of the left side of the scrotum, a position explained by the occupation of the spinner.
4. The etiology appears to depend on chronic irritation, the result of friction and contact with oil.
5. It is doubtful if the condition is preceded by an innocent stage.
6. The disease is similar in general features to other forms of cutaneous cancer and equally malignant.
7. The only hope of successful treatment lies in early and radical operation.

Through the courtesy of the members of the honorary staff of the Manchester Royal Infirmary we are enabled to record the cases in this series.

THE REMOVAL OF A PAPER FASTENER BY DIRECT PERORAL BRONCHOSCOPY

AFTER ITS IMPACTION FOR TWENTY-ONE MONTHS IN THE LEFT BRONCHUS.

BY

HERBERT TILLEY, B.S., F.R.C.S.,

SURGEON, EAR AND THROAT DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL, LONDON.

[With Special Plate.]

THE case here recorded has so many features which should be of practical interest to every class of practitioner that I have thought it worthy of record.

On Saturday, October 2nd, 1920, J. H., aged 5; swallowed a paper fastener. A violent fit of coughing immediately occurred and lasted about five minutes; this was accompanied by "pain in front of the left chest, which passed off in some three hours." Four days later, while at a children's party, such an alarming fit of coughing came on that the child's father and doctor were sent for and the patient was taken home in a motor car. He remained in bed for a month with symptoms of "acute bronchitis of the left lung." As the symptoms did not clear up a skiagram of the chest was taken on November 29th, but the result was so imperfect that it afforded no clue to the cause of the trouble. From that date to the removal of the foreign body the father states that the child "was always bronchial and short of breath," and "the noise he made at night was like air passing through a small hole."

On different occasions he would "suddenly get cold and the temperature rise as high as 104°; the attacks sometimes ended with vomiting followed by a sound sleep; then all would be well again until similar symptoms reappeared." In June, 1921, his tonsils, which were much enlarged, were enucleated, because "it was thought that they kept up the bronchitis," but the chest symptoms were in no way benefited by the operation.

Since August, 1921, the attacks of pyrexia occurred every two or three weeks, and especially after any exertion such as walking; in the meantime the appetite was failing and milk became the favourite food. A further consultation was held and the question of removing the appendix was discussed. During June, 1922, the child was so far from improving that Dr. Batty Shaw was then asked to see him, and I appended some brief notes which he sent me of the physical signs which he found in the patient's chest. The chief amongst them were "expansion of the chest very poor, nearly all breathing being done by the diaphragm. The right chest, however, expanded a little, but the left, especially in the lower part in front, collapsed on inspiration; moreover, the left lung behind was dull on percussion, vocal fremitus was normal, and I heard a rle or two."

In view of the history of the case, and that the physical signs were chiefly located in one (the left) lung, Dr. Shaw advised that the chest should be "screened," and Dr. Salmond's services were enlisted. He clearly demonstrated that the foreign body was lodged in the left bronchus with the clips fully spread and pointing upwards (see Special Plate), a condition of things which made the question of removal difficult, not without danger, but nevertheless possessed of fascinating problems to the practical endoscopist.

(I take this opportunity of thanking Dr. Batty Shaw for asking me to help him in the matter.)

Some of the difficulties were obvious. We could be sure that the points of the fastener would be invisible and embedded in the walls of the bronchus. In the early hours of the accident each inspiration would suck downwards and deeper into the bronchus the flat piston-like head of the foreign body, while the expiratory blasts of coughing would force the points of the wings into the soft contracting walls which surrounded them.

Furthermore, it might safely be assumed that the foreign body would be embedded in vascular granulations which would bleed on the slightest touch and thus obscure the small field available for operative manipulations. For the same reason a good deal of time would necessarily be spent in checking the haemorrhage.

Finally, one knew that in a child of 7 years only a tube of narrow calibre could be employed, and through this a long and slender forceps would have to be passed and its grasp directed by monocular vision. In an attempt to neutralize

this last handicap, I spent several hours in removing paper fasteners which were firmly fixed in rubber tubing of a size corresponding to that of the patient's bronchus.

The value of this preliminary practice cannot be overestimated, because there is no limit to the training of co-ordinated movements between the eyes and the fingers. Those *must* work in harmony, for although the experienced eye may see the foreign body, if the hand be unskilled its work will frequently end in failure, and too often the extent of this has only been revealed during the *post-mortem* examination on the patient.

Operation.

At 7 a.m. on June 29th a hypodermic injection of 1/100 grain atropine was given, and a second injection of the same amount at 9 a.m.; the object of this was to check the secretion of mucus in the lower air passages. Children tolerate atropine well.

At 10 a.m. Dr. Felix Rood administered open ether until the laryngeal reflex was abolished, and continued with a mixture of chloroform and oxygen during the remainder of the operation. The help he rendered me in many ways was invaluable.

A bronchoscope, modelled on the Chevalier Jackson principle by Irwin Moor, was then passed through the glottis into the left bronchus, and just beyond its distal end a mass of granulations could be seen. To this was applied a small swab of gauze moistened with equal parts of a solution of 10 per cent. cocaine and adrenalin chloride. After an interval of some five minutes I removed an oedematous granulation about the size of a green pea. The oozing of blood and mucus which we anticipated necessitated oft-repeated swabbing, and it was at least ten minutes before a reasonably dry field enabled me to detect the foreign body.

By means of Jackson's side-gripping forceps it was now possible to secure and dislodge the lower point of one wing of the paper fastener and to manoeuvre it just within the bevelled end of the bronchoscope. After further bleeding had been checked the second wing was secured, and finally tube, forceps, and foreign body were withdrawn together.

The patient recovered quickly and left the nursing home two days after the operation. I saw him again on July 6th; he appeared to be quite well, and the physical signs in the left lung (vide supra) had practically disappeared.

General Considerations.

1. Probably the first and most important lesson to be learnt from this case, and from so many others of like nature which have been reported, is contained in the history of the symptoms which followed the entry of the foreign body into the lower air passages. It should teach all practitioners that the sudden onset of cough associated with unilateral pulmonary symptoms in a previously healthy child is very suggestive of the inhalation of a foreign body. If this be granted, it follows that no method of examination should be neglected until all doubt upon the point is set at rest.

In the present case the history was clear enough and the patient was "screened," but unfortunately the negative was so defective that it led to the assumption that the symptoms were not due to a foreign body; consequently the treatment of the pulmonary symptoms was ineffectual, and caused much anxiety to the parents on account of the continued ill health of their child.

2. Therefore the second lesson we learn is that it is very unwise to rely on any one method of investigation, and particularly so when the means employed are imperfect. If an expert radiographer had examined the patient in the first instance the diagnosis would have been clear, and the treatment obvious, immediate, and probably successful.

On the other hand, let us suppose that a child is snoring from symptoms very suggestive of the inhalation of a foreign body into the lower air passages, and yet no history of the accident has been obtained. This has often happened in the case of children owing to their nervousness or to the fear of scolding or punishment. Furthermore, let it be assumed that the foreign body is a fish-bone or some substance not impervious to the x-ray. What course should be pursued? To this question there is only one answer—namely, look and see; and herein lies the inestimable value of the bronchoscope, both from the point of diagnosis and immediate treatment.

3. One more word about symptoms. Violent fits of coughing, unilateral emphysema, and localized fine crackling râles are common and early signs of the accident under discussion. These will vary with the nature, situation, size, and shape

of the foreign body, and their severity may alter from time to time if there should be any alteration or shifting of its position. Later on the symptoms may take the form of pulmonary collapse, consolidation, abscess, bronchiectasis, pleurisy, or the physical signs and constitutional disturbances may closely simulate those of tuberculosis, excepting the presence of the characteristic bacilli in the sputum. It would be nearly true to say that bronchiectasis in children is always caused by a foreign body. In adults such a factor is more likely to be overlooked or forgotten, as in a case reported by me in the *Lancet* of April 22nd, 1911, where a large piece of mutton bone had been impacted in the right bronchus for three years!

4. It will have been noted that the paper fastener lodged in the left bronchus, whereas most foreign bodies pass into the right because it is larger and more in the direct line of the trachea. From the same situation (left) I have removed two shawl pins, the cap of a lead pencil, and a portion of shrapnel casing (vide author's *Diseases of the Nose and Throat*, Lewis and Co.).

Anaesthetic.

My American colleagues may ask why a general anaesthetic was employed when Chevalier Jackson is able to report hundreds of consecutive cases successfully treated without any anaesthetic, local or general. My answer is that he is able to command the services of trained nurses and assistants who know his instruments, how these should be arranged for the operation, and how to clean them afterwards without ruining them. They understand the preparation of the patient before the operation and how to fix, immobilize, or alter the position during the operation. Each has his or her particular duty to be shared by no one else. They are the specialists of their profession, and happy is the surgeon who can command their services.

Such team work seems impossible in this country, even if there were sufficient material to make its organization worth while, and up to the present one has failed to persuade certificated nurses to confine their attention to, and become experts in, any one branch of work.

In consequence the endoscopist is driven to general anaesthesia in order to have his patient under complete control, and fortunately we enjoy the services of highly skilled anaesthetists who secure this end with the minimum of risk; at the same time they render the patient oblivious of what must often be a very uncomfortable and distressing experience.

This is scarcely the occasion to describe the technique and delicate manipulations which were employed to remove the foreign body in this particular patient. They will be familiar to experts but more or less devoid of interest to the average reader. Bronchoscopy is an art which bristles with important details. Its practice demands a degree of patience and gentleness not excelled by the expert angler with his dry fly. To grope blindly or to use force and lacerate delicate tissues which are often bathed in septic secretions is to betray a great trust and to show small respect for the sanctity of human life.

It will suffice to say that I used a Jackson bronchoscope—that is, with the little electric lamp at the distal end of the tube—and was therefore freed from the top-hammer of the proximal light carrier of Brining's instrument, which is still in common use in this country and on the Continent.

In conclusion, it seems a fitting opportunity for acknowledging the debt which endoscopists owe to Chevalier Jackson of Philadelphia, U.S.A., for his work in this department of medicine. Speaking for myself, and putting aside my appreciation of his many acts of personal kindness, it is impossible to appraise the value of his inventive genius or of his inspiring enthusiasm. Nor can the written word express my admiration and envy of the quiet but unrivalled skill with which he uses the instruments which bear his name.

THE next meeting of the Czech Tuberculosis Society will be held at Prague in the spring of 1923. This society was founded in 1920 for the purpose of promoting research in tuberculosis. Various scientific problems in connexion with the subject are being studied in the medical department of Prague University.

A POST-GRADUATE course in diseases of women and heart disease, lasting four days, was given at Franzensbad during the third week of September. In the following week a post-graduate course was held in Carlsbad; the lectures covered a number of different subjects, including diseases of the abdominal organs and disorders of metabolism.

A CASE OF ARSENICAL KERATOSIS FOLLOWED BY CANCER.

BY

HENRY C. SEMON, M.D., M.R.C.P.,

PHYSICIAN TO THE SKIN DEPARTMENTS, ROYAL NORTHERN AND
HAMSTEAD GENERAL HOSPITALS; DERMATOLOGIST TO
THE MINISTRY OF PENSIONS, ETC.

[With Special Plate.]

THE late development of epithelioma on a pre-existing basis of hyperkeratosis produced by prolonged arsenical medication is a rare phenomenon, and MacLeod,¹ in his textbook of skin diseases, states that only about fifteen authentic cases have been recorded in the literature. The part played by arsenic in the production of cancer has been disputed in some quarters,² on the ground that malignant disease is apt to develop in patches of psoriasis, etc., in which the drug has never been administered. If this objection be conceded, there still remain cases in which it was given over a prolonged period for conditions other than dermatological and in which epithelioma of the skin subsequently occurred.³ The argument is really beside the point, for most authorities are now agreed that the etiology of such growths is multiple, and that arsenic may be regarded as a predisposing factor of malignant degeneration, in virtue of its property of producing hyperplastic growth in surface cells, which are particularly exposed to traumatic and irritating influences, such as sunlight, variations of temperature, dust, friction, and recurring physical stimuli of all kinds.

Carcinoma *linguae*, from the etiological point of view, is more strictly akin to "arsenical" cancer than are "tar" or "x-ray" cancer, for in these the predisposing factors are local, while in the former two they may fairly be regarded as systemic (that is, syphilis, which produces leucoplakia, and arsenic, which produces an almost identical histological condition—hyperkeratosis). The credit of priority in the discovery of the relationship under discussion belongs to Jonathan Hutchinson, and the evidence which he first brought forward in 1887⁴ has since accumulated and received confirmation from the pens of such well-known dermatologists as Dubrenilh,⁵ Darier,⁶ and Hartzell,⁷ while, among the surgeons, Bland-Sutton⁸ published a case in this JOURNAL as recently as 1916.

The possibility of an impending increase in the incidence of the disease, as a result of the world-wide injection of arsenical compounds for syphilis, yaws, etc., has been raised by K. Ullmann.⁹ Salvarsan dermatitis, however, is an acute eruptive condition which tends to a *restitutio ad integrum*, and does not go on to keratoderma, which is the necessary preliminary to epithelioma.

Most of the cases of arsenical keratosis reported have followed the oral administration of the drug, but the dosage and the duration of treatment were by no means constant. In the cases published by Dubrenilh⁵ a keratosis of the palms and soles was noted as early as six months from the date of commencing the treatment, but the average incidence of cutaneous change is about two years, and the usual dose given has been from 15 to 30 minims of Fowler's solution thrice daily. The same author states that gastric and intestinal intolerance are danger signals, and that the occurrence of pigmentation, which usually precedes the development of keratosis by some weeks, is an absolute indication for cessation, or at least a prolonged intermission, of the drug. My own case conforms in every particular with the classical picture first enunciated by Hutchinson.

The patient, aged 40, who was referred to me by Dr. H. C. G. Pedler (Loodoo), had a more or less generalized psoriasis at the age of 12, and as the eruption was controlled by arsenic he persisted with its administration, and without further medical advice, for seven years. By this time (1901) pigmentation of the abdomen and warty growths on the palms and soles had developed, and his father consulted Sir Malcolm Morris, who at once recognized the cause, and forbade any further treatment with arsenic in any form. In 1905 he consulted the late Sir Lauder Brunton for oedema of both feet, one wrist, and the dorsum of the left hand.

In 1914 (that is, fourteen years after cessation of the drug) the hyperkeratosis on palms and soles was as obvious as ever, and a small painless ulcer made its appearance in or around one of the warty growths on the outer border of the right sole. The ulcer persisted, and was not regarded as serious apparently, for from February until July of the current year (1922) he received treatment by ionization in a country town. The size and appearance of the neoplasm, when I saw him on August 16th, is so well illustrated in the accompanying photograph (Special Plate, Fig. 1)

as to need no further description. The associated plantar and palmar keratosis is also clearly depicted (Figs. 2 and 3), and it only remains to say that the skin as a whole was remarkably dry, free from any abnormal pigmentation, showing a trace of psoriasis on the knees, elbows, and chest only. A slight degree of oedema, which pitted on pressure, and was therefore subcutaneous and not confined to the epidermis, was noted on the dorsal aspect of both feet.

The right leg was amputated through its lower third by Mr. T. T. Higgins on August 18th, and recovery was uneventful.

As in a somewhat similar case reported by Sir John Bland-Sutton,⁷ no glands, either in the popliteal space or in the groins, could be regarded clinically as containing malignant deposits. Bland-Sutton writes (*loc. cit.*): "It is said this form of cancer does not reproduce itself in the lymph nodes."

The histological appearance of the tumour is reproduced in the microphotographs (Figs. 4 and 5), and I am greatly indebted to Dr. G. W. Nicholson, of Guy's Hospital, for the following note on its structure:

"1. A squamous-celled carcinoma with extensive keratinization and formation of cell nests. The stroma is loose and oedematous, and contains numerous areas of inflammatory reaction. At its periphery the section is covered by hyperirradiated epidermis, with lengthened irregular papillae. Its centre is ulcerated, the base of the ulcer being occupied by granulations, most of which possess a covering of squamous epithelium obviously derived from the cells of the neoplasm itself. There is extensive infiltration of the cutis and subcutaneous tissues by columns of new growth, some of which are definitely within lymphatics.

"2. A section through a keratodermic nodule shows a strip of skin with irregular papillae, a well-marked stratum granulosum, and a greatly hypertrophied stratum corneum. The cutis and superficial layers of the subcutaneous tissue are fibrotic, the walls of the small blood vessels much thickened, and the sweat glands and their ducts small and atrophied."

The presence of thickened blood vessels noted by Dr. Nicholson affords a possible clue to the persistent oedema of the feet, and the paucity of sweat glands and the atrophy of their ducts doubtless account for the general xeroderma. The thickened blood vessels—the Wassermann reaction being negative in this case—may be presumed to have followed a preceding endarteritis, such as has often been described in the *post-mortem* records of the brains from fatal cases of salvarsan poisoning. If this theory is correct, it is not difficult to explain the oedema which is the result of the transudation of lymph through endothelium damaged or paralysed by the action of a protoplasmic poison.

Summary.

1. The case illustrates the danger of prolonged arsenical medication by the mouth.
 2. Where keratosis has occurred as a result of this the drug must be immediately suspended, and every effort made, by keratolytics, x rays, etc., to destroy the small warts and check their continued formation, and their pronounced tendency to spontaneous degeneration and necrosis.
 3. For a growth of the size depicted there is, of course, no effective treatment other than amputation. The site of the removal will depend on the situation of the tumour, the presence of infected glands, and other considerations of surgical importance.
- For small growths of recent appearance, without evidence of gland infection, the treatment by x rays or radium should receive a trial. Local excision is not recommended.

THE first course of lectures under the Charles E. Dohme Memorial lectureship was given at the Johns Hopkins Hospital, Baltimore, on October 10th, 11th, and 12th, by Dr. H. J. Hamburger, professor of physiology at the University of Groningen, Holland. The lectureship was established in memory of the late Mr. Charles E. Dohme, a well-known chemist of Baltimore, and its purpose is to promote the development of a more intimate relationship between chemistry, pharmacy, and medicine. The lectureship, which is of the annual value of 1,000 dollars, is open to scientists from any part of the world, and the selection of a lecturer is made by a committee representing the departments of pharmacology, chemistry, and medicine of the Johns Hopkins medical school.

PUERPERAL INFECTION MORTALITY IN WALES.*

BY

EWEN J. MACLEAN, M.D., F.R.C.P. LOND., F.R.S. EDIN.,
PROFESSOR OF OBSTETRICS AND GYNAECOLGY, WILKIN
NATIONAL MEDICAL SCHOOL.

[Dr. MACLEAN, having traced in considerable detail the historical basis upon which our present knowledge of puerperal infection rests, and having discussed the questions of definition and classification, continued:]

It would not be consonant with the title or purpose of this paper to pursue in detail the etiology and pathology of puerperal infection, but some consideration must be given to the important questions of its frequency and distribution.

Arnold Lea, writing in 1910, drew attention to the fact that the reports of the Registrar-General showed that in the British Isles during the previous forty years the mortality from puerperal infection had but slightly diminished, notwithstanding the revolution which had occurred in surgical practice by the application of the principles evolved by Pasteur and Lister. The lying-in hospitals only participated in the bottoming so far as midwifery was concerned, and in these institutions the mortality had been reduced to a minimum. Taking a quinquennial period of seventy years ago the puerperal death rate from all causes was 4.9 per 1,000 births, as compared with 4.2 for a similar period of sixteen years ago, and deaths from puerperal infection account for 50 per cent. of these rates. The Registrar-General's report for 1920 makes reference to the tale and toll of the intervening years.

In 1920 the number of deaths assigned to pregnancy or childbirth corresponded to a rate of 4.12 per 1,000 births, as against an average rate of 3.78 in the ten years immediately preceding and 4.12 for 1919.

The lowest level reached was 3.55 in 1918, so that the increase to 4.12 in 1919 and 1920 has been sudden as well as considerable, and when distinction is made between deaths ascribed to *septic* and to *other* causes it emerges that the increase is almost entirely due to sepsis, the rate for which is higher in 1919, and still more so in 1920, than in any of the preceding ten years. It may be significant or merely coincidental that the erysipelas mortality of 1920 is the highest since 1915.

The chief medical officer of the Ministry of Health in his report for 1921 is able to indicate some improvement in the number of deaths from puerperal sepsis as well as from other causes, the inclusive rate being 3.9 per 1,000 births, as compared with the 4.1 already quoted for the two previous years. He adds:

"The fact that in England 3,323 mothers lost their lives on account of childbirth last year cannot be regarded without grave concern. It is a matter which should receive the careful and continued consideration of teachers and practitioners of midwifery and of all responsible for making due provision for the mother at the time of her confinement."

Of the total number of registered births in England 54 per cent. were notified by midwives, and he points to the obvious importance of a high standard of practice by midwives being encouraged, and to that end recommends that in all districts, urban and rural, there should be an adequate number of competent, sufficiently remunerated, and, where necessary, a subsidized service of midwives. He stresses the importance of ante-natal supervision and urges the provision where possible of lying-in accommodation, not only for abnormal cases but for women who cannot safely be confined at home. But lest, like Mark Twain in his classic lecture on the Babes in the Wood, I should be guilty of saying nothing connoted by the title of the paper, I must focus the foregoing in its application to conditions prevailing in the Principality.

A recognized authority on the geographical distribution of puerperal infection in England and Wales—the late Dr. William Williams, the distinguished medical officer of health for the county of Glamorgan, whose friendship many of us were privileged to enjoy—found that the puerperal septic death rate varied from 1.4 to 3 per 1,000 in different centres, the maximum being reached in Lancashire and Wales, while many of the counties were represented by a figure below 1.4.

Deaths from accidents in childbirth, however, are most numerous in agricultural districts with a scattered population, and reach the minimum in London and its surrounding counties. This is generally attributed to the greater availability of skilled assistance in emergencies in the more densely populated districts.

Dr. Williams studied in detail the distribution of mortality in South Wales, and found that infection occurred most frequently amongst women attended by ignorant or untrained midwives, and that density of population, climatic conditions, and even the presence of zymotic diseases, such as scarlet fever and diphtheria, had little influence. Dr. Williams, as well as subsequent writers, and, indeed, every authoritative report dealing with the matter, draws attention to the exceptionally high puerperal mortality among women in Wales. In one period, when the average mortality from childbirth and childbirth in London was 3.9 per 1,000 births and in England and Wales 4.7, the figure for South Wales was 6.1 and for North Wales rather higher still. And again, in the puerperal mortality census for England and Wales, 1911-14, when the mortality rates per county were indicated by degrees of shading, there were only two black counties, both of which were in Wales—Cardigan and Merioneth—the qualification of a black county being that as many as 8.9 mothers died per 1,000 births. In the latest report (1920) of the Registrar-General the figures show that in the maternal mortality rate per 1,000 children born alive Wales is definitely higher than any or all parts of England, and, therefore, than the combined rate for England and Wales. This applies to county boroughs (5.79—England and Wales 4.42), urban districts (5.27—England and Wales 4.46), and rural districts (5.77—England and Wales 4.54), the consolidated Welsh rate being 5.52 as against 4.33, the average for England and Wales. For puerperal deaths due to sepsis the Welsh rural districts still hold, unfortunately, an outstanding position in the whole of England and Wales (2.22 per 1,000 live births, as against England and Wales 1.68).

I am indebted to Dr. Llewellyn Williams, of the Welsh Board of Health, for his kindness in furnishing a map and recent figures indicating the prevalence of puerperal infection in Wales, notifications received in connexion therewith, and the deaths ascribed thereto. There can be no doubt that many cases of puerperal infection are not notified, and that this is especially so in the rural districts. I have gladly accepted Dr. Llewellyn Williams's courteous invitation to co-operate with himself and his able staff in an investigation into the whole of this urgent problem.

Dr. W. Williams, in a communication on puerperal mortality to the Epidemiological Society of London in 1896, deals with many points common to the disease occurring anywhere and with some points having especial bearing on conditions in Wales. At to the higher mortality of puerperal infection in primiparae, he relates that in an epidemic investigated by him no less than 75 per cent. of the primiparae affected died.

Attention is drawn to the excessively high puerperal infection rate in Merioneth and Cardiganshire—two typical instances of purely agricultural and hilly counties—as compared with a low rate in Pembrokeshire, Anglesey, and Radnor, also purely agricultural but comparatively flat. The mining county of Glamorgan and the mixed mining and agricultural counties of Carmarthen and Carnarvon show a mean rate.

Of the counties, Glamorgan alone may be called "densely populated"—that is, with less than one acre per person. Flint had less than two acres, while the remainder may be termed "sparsely populated." The figures quoted tend to show that density of population is not a factor of much importance in determining puerperal infection, but rather that the higher mortality from both sepsis and the accidents of childbirth prevails in those counties which are mountainous, hilly, and sparsely populated, and where, consequently, locomotion is tedious and medical assistance difficult to obtain.

The Registrar-General of forty-five years ago said in one of his reports: "In North Wales, where the mothers are left to nature or to unskilful old women, the mortality is double that of London, and 9.4 mothers die to 1,000 children born." Dr. Williams admitted there was much truth in this remark, and that it was within his knowledge that in the counties of Merioneth and Cardigan, so prominent in their mortality rates, most of the confinements among poorer women were attended by untrained women; that similar conditions obtained in all the county districts, villages, and small towns of

* Presidential Address to the Cardiff Medical Society.

Wales; and that in Glamorgan puerperal infection was often spread broadcast in this manner.

When first appointed medical officer of health to the county of Glamorgan he was called upon to investigate an epidemic of puerperal infection in the Garw and Ogmore valleys, in both of which, and especially the Garw, the disease had acquired the reputation for years of being almost endemic. The two valleys are certainly topographically distinct, and at that time, at all events, there was no appreciable interchange between their midwives. On the basis of his investigations and the experience of a local practitioner he makes the interesting statement that the majority of cases confined in houses infected with scarlet fever escape puerperal infection, and that if occasionally a lying-in woman takes scarlet fever she does not develop puerperal infection symptoms and generally recovers. One of Dr. Williams's observations recalls the saying of Gordon of Abdriceu: "The infection in this disease is most subtle, persistent, and portable, and more difficult to get rid of than in almost any other disease."

Many further facts and figures might be furnished to support the view that in Wales the subjects of puerperal mortality, and especially of puerperal infection, still afford an outstanding problem which all bodies and persons executive concerned should strive to solve. Ultimately I believe the great betterment will come along the lines recommended in the second report of the Welsh Consultative Council, but meanwhile much can be done by the intelligent and conscientious observance of preventive measures and by the harnessing of the new facts which evolve from laboratory and clinical research.

PREVENTIVE MEASURES.

The range of prophylaxis must include pregnancy, labour, and the lying-in period.

1. *During pregnancy* attention should be directed to the general health, urinalysis, personal hygiene, and the careful treatment of erythematous or eczematous conditions of the vulva, vaginitis, or fistula in ano, etc. Particularly in primigravidae a systematic pelvic examination is of the greatest importance.

2. *During labour* the selection and preparation of the lying-in room and the exclusion of all persons suffering from diseases such as tonsillitis or any form of septic infection call for attention. The arrangement of the bed and the preparation of the patient, her clothing, and detailed disinfection of the vulva as the centre of the "field of operation" are of the utmost value. As regards vaginal douching, this practice in normal labour is unnecessary and may be harmful, the essential point being to carry out complete antisepsis of the vulva. Too much importance cannot be attached to the disinfection of the hands and the intelligent use of rubber gloves. The number of vaginal examinations during labour should be limited by real requirement, and the same comment applies to the number of obstetrical operations, including not only instrumental interference, but the most dangerous of all obstetrical operations, the manual removal of the placenta, involving, as it does, the definite risk of the direct inoculation of organisms on the placental site. There are instances, of course, where that risk must be accepted—as, for instance, in post-partum haemorrhage or cases where full time has been allowed and where the various methods of expression have been thoroughly tried without effect. The retention of a small portion of membrane within the uterine cavity does not in itself justify manual exploration. Vaginal or intrauterine douching after normal labour is not called for, but should be practised only when there is reason to surmise that by hand or instrument organisms have been introduced. The repair of injuries produced during delivery should be undertaken with the fullest regard to aseptic and antiseptic precautions.

3. *After delivery.* A careful ritual observed during labour is too often relaxed or abandoned forthwith, whereas the maintenance of asepsis is of prime importance, and this involves the carrying out of general and local measures to that end; especial danger attaches to careless sponging of the vulva, and, as far as possible, all manual interference with the vulva or vaginal orifice during the early days of the puerperium should be avoided.

There is but time to put forward these few indications on preventive lines and to add that we, and all others interested in this profoundly important topic, must feel that there is much yet to be learned both at the bedside and in the research laboratory, and that the improvement we seek on behalf of the community, and in particular on behalf of

Wales, "can only be brought about by a full appreciation of all that is known of the etiology of the disease, and an adequate sense of the responsibility on the part of all those brought into relation with the lying-in room."

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

"HAEMORRHAGIC" CHICKEN-POX.

By the courtesy of my colleagues, Dr. Alexander and Dr. Binns (the latter being in charge of the patient), I am able to submit the following notes of an interesting and very unusual case of chicken-pox.

A girl child, aged 3, was seen to be sitting up in bed eating a piece of cake; she was to all appearance perfectly well. Pulse 84, respirations 16, temperature normal. Urine clear, stools normal. Without any initial illness there had appeared some spots on her skin on November 3rd, which by November 5th had turned black. On November 6th these spots were noted to present the following approximate number and appearance: right hand 3, right forearm 9, right arm 18; left hand 4, left forearm 9, left arm 15; face 34; front of chest and abdomen 36. There were less than 150 lesions on the whole skin.

One lesion, selected for close examination, was situated near the apex of the right scapula. It was crenate in outline, irregularly lozenge-shaped, its long axis being parallel to the natural folds of the skin in this region; the appearance was exactly that of a chicken-pox vesicle recently collapsed, except that the contents were now perfectly black, and apparently consisted of dried blood. Immediately around the vesicle was an area of pale crimson skin, which in its turn was surrounded by a faint purplish area, having much the appearance of a recent bruise. The whole of this area of discoloration measured about 14 by 15 mm.; it was covered by a half-sovereign. Nearly every complete lesion was surrounded by a similar ecchymosis, and some of the aborted lesions showed a very slight but unmistakable discoloration around them. There had been epistaxis. There was a bruise under the left eye on the upper part of the cheek. No subconjunctival haemorrhages were noted. There were three black spots on the tongue, one on the lower lip. Both labia majora were ecchymosed.

The child was seen again on the following day, November 7th, and her somewhat anaemic condition was noted. Otherwise she appeared to be well, and was playing with her brothers and boys. A small subconjunctival haemorrhage was noted in each eye. The left eye was surrounded by ecchymoses or bruises apparently associated with spots. Numerous brownish bruises were noted on the right leg and some on the right arm.

The case was unquestionably one of chicken-pox of mild degree, as well as could be gauged from the number of the spots and the absence of constitutional symptoms. It seemed probable that some idiosyncrasy in the child, of which this was perhaps the first intimation, had led to these haemorrhages and bruises. I have heard of one similar case, in the person of a lady in middle life who had an attack of chicken-pox, but do not know whether she suffered from haemophilia or not. I should like to hear of similar cases.

London, S.E.

POTASSIUM PERMANGANATE IN DERMATOLOGY.

The treatment of skin diseases by potassium permanganate as advocated by S. Feldman and B. F. Ochs in the *Archives of Dermatology and Syphilis*¹ is not in any way a new form of treatment.

My friend and teacher Dr. Douglas Heath of Birmingham has been using potassium permanganate quite extensively for a number of years, not only for the skin conditions mentioned by Feldman and Ochs, but also and chiefly for the treatment of the moist type of lupus vulgaris, which it dries up in a very short time. For these cases Dr. Heath advocates the use of a saturated solution of potassium permanganate. Personally I have been using with very satisfactory results an alkaline potassium permanganate paint in the treatment of Boeckhart's impetigo. I use the following solution:

R Pot. permang.	gr. xv
Sed. bicarb.	gr. x
Aquam	3j

It is applied once a day to the lesions and skin around them after letting the pus out with a needle.

Birmingham.

Reports of Societies.

PERNICIOUS ANAEMIA.

A discussion on pernicious anaemia took place at the meeting of the Medical Society of London on November 13th. The President, Lord Dawson of Penn, was in the chair.

Dr. P. N. PANTON, in opening the discussion, said that he, with two colleagues, had succeeded in collecting 117 cases from the records of the London Hospital over a period of eleven years, and all but sixteen of these cases had been followed up. Pernicious anaemia was an uncommon, but not a rare condition. It ran a characteristic course, almost invariably fatal. Medicine had little or no control over the chronic condition, it appeared to play no part in the rare cases of recovery, and probably the treatment of the more characteristic cases had even less influence on their course than those in charge of them supposed. The underlying factor was hidden; it might be a single entity or a group of conditions. Pernicious anaemia was a condition of severe anaemia, to be explained neither by the history obtainable from the patient nor by a study of his clinical condition. The haemolysis was slow and continuous, and associated with the clinical condition was a characteristic blood picture, of which the main features were a severe loss of red cells (and certain changes in the cells) without a corresponding great loss of haemoglobin. It was this combination of the clinical study and the blood picture which rendered the diagnosis relatively simple. Complicating conditions were very rare, with the exception of subacute combined degeneration of the cord. There were certain definite and constant *post-mortem* changes. Associated with the clinical study were oral sepsis, achylia, and pyrexia. There was no striking evidence that oral sepsis was an aetiological factor. Many of the patients with whom he had had to deal received the most thorough dental treatment, with disappointing results. Not a single case recovered as a result of the treatment of the dental sepsis. Achylia had attracted considerable attention. Pernicious anaemia might occur, though rarely, without achylia. A severe secondary anaemia, particularly if prolonged, might be associated with achylia, and if that secondary anaemia was cured the achylia might still persist. Too much attention should not be paid to achylia as a possible cause; rather he would regard it as part of a vicious circle. Conceivably it might be an important predisposing factor. Pyrexia was an extremely constant accompaniment of pernicious anaemia. It was present at one time or another in ninety of the cases included in his investigation. As a rule it coincided with exacerbations of the disease. This fact had been used as an argument for an infective agent, but the haemolysis which was going on would alone be sufficient to account for the fever. As for treatment, it was, of course, desirable that the oral sepsis should be attended to, but he was against any wholesale extraction of teeth. Of two patients shown to the Society that evening, representing two of the very few successful cases, one had marked pyorrhoea still present, and the other still had carious teeth. Vaccine treatment was practically of no value. Benefit came to the patient by treating his achylia. Treatment by splenectomy never seemed to the speaker to have any theoretical or practical justification. In his cases it was performed only in one, and the patient lived for three years afterwards. A few cases were treated by blood transfusion; this was a course which should only be adopted for some specific reason. One lady, for instance, much desired to live to see her son, who was returning from abroad, and her life was prolonged for six months by blood transfusion. It was possible that the value of treatment by arsenic had been overestimated; its apparent efficacy might depend upon the period in the "wave" of the disease at which it was administered. He described a number of conditions allied to pernicious anaemia, in which the connecting link was internal haemolysis, and in all of which the blood picture of pernicious anaemia was closely simulated.

Dr. A. MAITLAND-JONES, who was associated with Dr. Panton in this investigation, gave further details of the 117 cases. It appeared that the average number of remissions in each case was about two; if the number exceeded two it might go on to five or six. The average duration of remissions was about four months; a longer period than four months was uncommon, a longer period than nine months very rare. The average red cell count when the patients

came into hospital was 1,300,000, and when discharged on remission 2,400,000. It might be supposed that the blood count approached somewhere near to normal during remissions, but this was not so. The recovery of the blood was not so marked as might be expected. The number of red cells during the remission period rarely exceeded 3,500,000. Yet the patient was greatly improved, and it seemed as though his feeling of well-being during remission was not so much dependent on an increase in the red cells as on an increase in blood volume. A number of cases had no remissions at all. This applied in 18 out of the 101 cases which had been followed up; the average duration of these cases was nine months from the beginning of symptoms. The average duration of the whole 101 cases from the beginning of symptoms was twenty-eight months, and from the time of admission to hospital thirteen months. Of these 101 cases 93 were dead. Of the 8 which were alive, 1 had been alive for seventeen years, 1 for fourteen years, 2 for eight years, 2 for seven years, and the others for shorter periods. One man who was brought before the Society that evening was an apparent cure; he was admitted thirteen years ago into the London Hospital, when his red cells were 700,000, and he had complete achylia. His blood count was now 5,000,000, and he still had complete achylia. Another case, a woman, was an example of arrested disease. Her blood count was 1,300,000 in 1909, and at the present time it was 4,400,000.

Dr. A. F. HUNTER devoted himself to a consideration of the part played by achlorhydria in the pathogenesis of pernicious anaemia. He believed that achlorhydria was almost invariably the predisposing cause. It had been suggested that it was secondary to the anaemia, but he had collected twelve cases in which it was known to have preceded the onset of anaemia by periods varying between one and twelve years. Moreover, it had been found in the early stages of the disease when the haemoglobin percentage was still as high as 80. There was nothing specific about the achlorhydria which disposed to pernicious anaemia, as it was the absence of free hydrochloric acid, and not the cause of this absence, which was the important factor. In the majority of cases the achlorhydria was probably due to constitutional achylia gastrica—an inborn error of function. Several authors had lately drawn attention to the occurrence of pernicious anaemia as a family disease, and it seemed probable that achylia was the inherited factor. The absence of gastric juice resulted sooner or later in secondary chronic gastritis, and, even after many years, in partial atrophy of the mucous membrane. But these were secondary to, and not the cause of, the achylia, which was just as complete in the absence of all pathological changes as it was with severe atrophic gastritis. In considering the possibility of subacute combined degeneration of the spinal cord being associated in rare instances with cancer of the stomach, Bell and he had suggested that if this ever really occurred it would probably be in one of the 50 per cent. of cases of gastric cancer which were accompanied by achlorhydria, when it would be secondary to the latter, and not due directly to the cancer itself, and that it would also certainly be associated with pernicious anaemia. Achlorhydria not only favoured infection of the intestine, but it resulted in the arrival in the intestine in an unaltered condition of proteins taken in the food. The result was that the digestion of protein, though eventually complete, was delayed, and an undue proportion remained in the lower part of the ileum in a form in which it could undergo bacterial decomposition. Thus achlorhydria not only predisposed to intestinal infection, but it resulted in the provision of material which was likely to form toxins, one of which might be presumed to be haemolytic and the cause of the anaemia, another a neuro-toxin causing subacute combined degeneration of the cord, and possibly a third acting upon the bone marrow and causing it to form an abnormal type of red cell. Every patient with achlorhydria should be regarded as a potential case of pernicious anaemia. Hydrochloric acid should be given in adequate doses at every meal for the rest of the patient's life, and his teeth should be put in perfect order, and kept so by periodic treatment. The treatment of pernicious anaemia should consist in radical treatment of the oral sepsis, the administration of hydrochloric acid, the regular use of sour milk, and inoculation with a vaccine prepared from streptococci isolated from the patient's own duodenum by means of a Ryle's tube. In most cases $\frac{1}{2}$ to 2 drachms of dilute hydrochloric acid added to 4 or 6 ounces of water to make a strength equivalent to that of the gastric juice was required to produce an approximately normal curve of acidity with a fractional test meal. If lemon

juice and sugar were added the mixture made a palatable beverage. In most cases symptomatic treatment was also required for the anaemia, and he was inclined to recommend transfusion, and possibly splenectomy, in addition to the usual arsenic. With early diagnosis the prospects of successful treatment on those lines were favourable.

Dr. J. J. CONYBEARE said that the records of all cases of pernicious anaemia at Guy's since 1850 had been collected. Dr. French brought the series up to 1909, and Dr. Campbell and himself completed it to the beginning of the present year. The records suggested that the disease had become more common. During the period 1909-22 the average number of cases in the hospital each year was 5.4, whereas when the records were first taken the number was only 1 per annum. In the cases which he and his colleague had collected during the last fourteen years some gastro-intestinal symptoms, either vomiting, abdominal pain, or diarrhoea, occurred, concurrently with the development of anaemia and before the patients had anything in the way of arsenic, in 35 per cent. Pigmentation was present in a great many more cases than was expected. Dr. French's cases, tabulated earlier, showed 18 per cent. to have pigmentation in the skin and 3 per cent. in the mouth. In the later cases, excluding all pigmentations due to arsenic, 12 per cent. had pigmentation on the skin and 5 per cent. in the mouth.

Dr. C. PRICE-JONES showed diagrams to illustrate the great variations in the size of the blood cells in pernicious anaemia. In healthy persons the red cells were homogeneous; in pernicious anaemia they were heterogeneous. In this condition the basic thing was the formation of large cells which were readily haemolysed, and it was this haemolysis which gave rise to the anaemia.

Dr. H. L. TINY mentioned a nign case which he had recently seen. At the autopsy, on the femur being cut through a sharp dividing line was discovered in the bone marrow, on one side of which, when examined through the microscope, there was an evident condition of pernicious anaemia, and on the other side one just as evident of aplastic anaemia. The same curious condition was found in the ilia and other bones.

Dr. F. J. PORTYON referred to the question of anaemia gravis in children, which many authorities looked upon as aplastic anaemia, but which closely resembled pernicious anaemia in adults. What was called an aplastic anaemia in children was not purely aplastic. This disease advanced in waves and went back again, just as in adult pernicious anaemia. If it was essentially a pernicious anaemia in the young, one must eventually learn something from a study of its special features, and if it was a different disease it was equally worthy of study in relation to the other. He believed that the proper study of all these blood affections was to some extent hindered by a continued adhesion to blood pictures.

Sir PERCY BASSETT-SMITH said that in sprue (which had been mentioned by one speaker) there was an extremely low red cell count; but sprue differed from pernicious anaemia in that the colour index was low, so that it was true secondary and not primary anaemia.

Dr. GEORGE RIDDOCH gave some account of the neurological manifestations and of the histological evidence *post mortem* of gross lesions found in the spinal cord, mainly, but not exclusively, in the mid-thoracic portion. Subacute combined degeneration of the cord, which had been associated by clinicians with pernicious anaemia, might appear with little or no evidence of blood changes. On the other hand, cases with gross changes of the blood might go through all the stages to death without any gross manifestations of cord involvement.

Dr. M. E. ALEXANDER referred to the introduction in America of germanium dioxide as offering a possible method of treatment, being less toxic than arsenic, and causing in laboratory animals a distinct rise in the number of blood cells. He had employed this in six cases, and while theoretically it ought to be of use, practically the results were negative, and, as the new remedy was expensive, it was as well to put this on record.

Dr. PAXTON, in a brief reply, referred especially to children's anaemias. The diagnosis of blood diseases in children was extraordinarily difficult. He had never been able to convince himself that he had seen a case of pernicious anaemia in a child under 12 years of age. He would consider a low colour index to be a great argument against these children's anaemias being regarded as pernicious. He agreed that not too much should be made of the blood picture, but unless a very careful blood picture was made there would be a great deal of clinical confusion.

HYDROCEPHALUS.

At a meeting of the Edinburgh Medico-Chirurgical Society held on November 2nd, with the President, Sir ROBERT PHILIP, in the chair, Mr. JOHN FRASER and Dr. N. DOTT read a communication on hydrocephalus. The normal anatomy and physiology of the parts were first described. The cerebro-spinal fluid was produced from the choroid plexus and from the perivascular spaces. It was absorbed normally by the Pacchionian bodies, the arachnoid villi, the arachnoid mesothelial cells, and by the cortical lymphatics. The three possible factors at fault were overproduction of fluid, blockage of its channels of circulation, or diminished absorption. With the exception of the true congenital type the condition was always due to blockage, the seat of obstruction being either inside the ventricular system or between the crura and the edge of the tentorium cerebelli; overproduction of fluid practically never occurred. Factors in the etiology were birth haemorrhages, pressure by tumour, congenital syphilis, and basal meningitis. It was necessary to investigate the origin of the condition, whether the block was intra- or extra-ventricular, and if intraventricular the actual seat of obstruction. A solution of phenolsulphonophthalein was injected into the ventricles, and lumbar puncture was carried out twenty minutes later, the presence of colouring matter showing that the lesion was extraventricular, its absence that it was intraventricular. If intraventricular the seat of the lesion was determined by ventriculography, oxygen being used to replace the cerebro-spinal fluid withdrawn. X-ray examination of the head in different positions showed whether the obstruction was situated in the aqueduct, the foramen of Monro, or in the roof of the fourth ventricle. The operative treatment was described in detail. In extraventricular cases ligation of the carotids was stated to be the best treatment. The communication was illustrated by lantern slides, and cases which had been under treatment were shown; the oxygen apparatus was also demonstrated.

Professor EDWIN BRAMWELL spoke of the value of ventriculography in the diagnosis of cerebral tumour. He described a case in which a woman, after an illness of ten days, had died with cerebral symptoms, a simple cyst of the choroid plexus blocking the foramen of Monro being found *post mortem*. Dr. CLAUDE B. KER referred to cases of cerebro-spinal meningitis in which large amounts of fluid were withdrawn by repeated puncture, and expressed the view that in these cases there was overproduction of fluid. Mr. D. M. GREIG and Miss HERZFELD emphasized the importance of syphilis in the etiology and the value of novarsenobillon in treatment. Dr. TRAQUAIR and Dr. J. S. FRASER also spoke, and Mr. JOHN FRASER replied.

Influenza, Encephalitis, and Cerebro-spinal Meningitis.

Dr. ALEXANDER JAMES then read a communication on some etiological considerations in influenza, cerebro-spinal meningitis, and epidemic encephalitis. Dr. James believed that recent outbreaks of influenza were simply recrudescences of the epidemic which began in 1889. Charts of the mortality and notification records were shown demonstrating the close relationship which the cerebro-spinal meningitis epidemics of 1907-08 and 1914-19 had with the various outbreaks of influenza since 1889. The similarity was less striking now than formerly, since epidemic encephalitis had been recognized as distinct from cerebro-spinal meningitis. Epidemics of these two conditions often occurred together and had many symptoms in common. The inference was that their etiology was similar. Referring to the frequency with which outbreaks of these diseases were associated with outbreaks of influenza, Dr. James expressed the view that influenza had a devitalizing influence on the central nervous system, lowering its resistance to the organisms or toxins producing these conditions. In his opinion disseminated sclerosis and paralysis agitans sometimes occurred as sequels of epidemic encephalitis.

Professor EDWIN BRAMWELL suggested that influenza encephalitis and cerebro-spinal meningitis were possibly predisposed to by some common factor. Outbreaks of poliomyelitis were sometimes related to those of cerebro-spinal meningitis though their etiology differed. He had never met with a case of disseminated sclerosis arising as a complication of encephalitis. Dr. CLAUDE B. KER also thought that influenza, cerebro-spinal meningitis, and encephalitis were essentially different diseases, possibly with a common predisposing factor.

Clinical Cases.

Professor LOVELL GULLAND showed two cases. One was a case of Addison's disease with a previous tuberculous history; the patient was improving under tuberculin and large doses of adrenalin. The other case was that of a woman of 47, who had developed polycythemia vera with the onset of the menopause; she was improving under x-ray applications to the long bones.

Dr. CRANSTON LOW showed several cases of diseases of the skin, including one of lupous carcinoma, which after scraping was being treated with massive doses of radium.

JOINT MEETING IN MANCHESTER.

A joint meeting of the Manchester Medical Society and the Liverpool Medical Institution was held in the University of Manchester on November 1st, with Sir WILLIAM MILLIGAN in the chair.

The Ductless Glands and Skin Affections.

Dr. R. W. MacKENNA (Liverpool) read a paper on "The relation of the ductless glands to some affections of the skin." He began by pointing out that the subject was one beset by difficulties, but he believed that the elucidation would come from clinical observation rather than from laboratory experiments. After dealing with the definite cutaneous changes associated with hypo- and hyper-thyroidism he showed how thyroid substance had been administered, more or less empirically, in psoriasis, ichthyosis, eczema, lupus, keloid, scleroderma, and other diseases of the skin, sometimes with striking benefit, but sometimes with little apparent result. He then proceeded to review the action of the other ductless glands, mentioning particularly the influence of the parathyroids on calcium mobilization, the action of the suprarenals in influencing pigmentary changes in the skin, and their possible relationship to acanthosis nigricans and neuro-fibromatosis. Finally he discussed the internal secretion of the gonads, more particularly with reference to their effect on the growth of hair; hirsuties in women he definitely correlated with diminished ovarian secretion.

Angina Pectoris.

Dr. JOHN HAY (Liverpool) offered some observations on a case of angina pectoris in which the electrocardiogram showed indications of a right bundle lesion, and in which the dominant site of the pain was epigastric. He discussed the significance of abnormal electrocardiograms in patients suffering from angina, and the view that an electrocardiogram showing marked deviation from the normal Q.R.S. complex was an indication of cardio-sclerosis. In the case described the electrocardiogram was of the type indicating some interference with the right branch of the bundle. Examination revealed no organic block, but there was some increased fibrosis and atheroma of the coronaries. Of 25 anginal patients who were electrocardiographed, 10 showed definite abnormality in the Q.R.S. complex. Of these, 8 died, as compared with 15 anginal patients with normal electrocardiograms, of whom 6 died during a similar period of time—that was a comparison of an 80 per cent. with a 40 per cent. mortality. From these and other figures the justifiable inference was that in angina pectoris an electrocardiogram showing branch bundle lesion or arborization block made the prognosis much graver. Reference was made to those cases in whom epigastric pain was the dominant symptom. Numbers were given showing the ratio of incidence to be 16 epigastric anginas in a total number of 288 patients. In the one patient before mentioned the pain was primarily epigastric in site, but examination revealed no lesion of the liver, gall bladder, or gastro-intestinal tract to account for the pain. Special attention was drawn to the importance of angina minor, the earlier manifestations of which are unobtrusive but significant, more particularly the substernal oppression or feeling of substernal distension which is induced by effort and which disappears with rest.

Indications for Cholecystenterostomy.

Mr. T. C. LITTLE JONES (Liverpool) discussed the indications for cholecystenterostomy. His usual practice, he said, was to anastomose the gall bladder to the duodenum, and in one case where a fistula was found between the gall bladder and the colon the fistula was re-formed with satisfactory

results. This operation was of considerable value in relieving the symptoms in cases of malignant disease of the head of the pancreas. In cases where difficulty was experienced in removing stones from the common duct he had found the transduodenal route a good means of access. The duct ran for about half an inch in the wall of the bowel, and could be safely incised for this distance in removing stones. It might be difficult to find the papilla, but by using a probe or pressing on the duct above it could generally be identified. The pains so commonly seen after cholecystectomy might be due to the constant flow of bile into the duodenum, due to the relaxation of the sphincter of Oddi.

CARDIFF MEDICAL SOCIETY.

At a meeting of the Cardiff Medical Society held on November 8th Professor ERWIN J. MACLEAN gave his presidential address on puerperal infection mortality in Wales. The address is printed this week at page 975.

Colloidal Silica.

Dr. W. H. TYTLER, bacteriologist to the National Memorial Association, gave a demonstration in the absence of Professor S. L. CUMMINGS. Recent work in the Tuberculosis Department of the School of Medicine and the Welsh National Memorial Association showed, he said, that silica colloid had a marked power of inhibiting the action of "complement," and thus prevent the lysis and destruction by bacteria of the blood fluids. The specimens illustrated how completely the lytic effect of fresh blood upon typhoid bacilli was stopped by the presence of colloidal silica. In one series of preparations serial dilutions of a typhoid broth culture had been mixed with an equal volume of sterilized normal salt solution, and from this mixture a measured volume had been added to an equal amount of fresh normal human blood, the preparations being then placed in the incubator at 37° C. for one hour and forty minutes. At the end of that time the whole contents of each tube were transferred to the surface of a tryptic agar slope and incubated over night. Very few colonies developed on the agar, showing that the bacilli had been killed by the lytic action of the blood.

In the next series similar serial dilutions of a typhoid broth culture had been mixed with an equal volume of silica colloid, and afterwards equal volumes of the mixture and fresh human blood were prepared and treated as in the former case. In this series the tryptic agar slopes were seen to be covered with a thick growth of typhoid bacilli, showing that in spite of the presence of the lytic substances of human blood the bacteria had been preserved from destruction during the period of one hour and forty minutes' contact at blood temperature. That this prevention of lysis was due to interference with "complement" was shown by the next series of tubes in which the complete inhibition of lysis of sensitized red blood corpuscles by the presence of silica colloid was demonstrated.

Dr. Tytler concluded that these observations might, perhaps, have a bearing on the action of silica in leading to the establishment of bacterial diseases in the tissues to which attention had recently been drawn by Gye and Kettle; while the inhibition of cytolytic activity noted might explain the fact, observed by Mavrogordato in South Africa, that macrophage cells containing ingested silica dust were protected from "antolysis" and digestion in the lymph spaces.

X-RAY DIAGNOSIS OF GASTRIC AND DUODENAL CONDITIONS.

THE 700th ordinary meeting of the Brighton and Sussex Medico-Chirurgical Society was held on November 2nd, with the President, Mr. A. J. HURCHMAN, in the chair, when Dr. W. BARINGTON PROWSE read a paper on "X-ray diagnosis of some abnormal conditions of the stomach and duodenum." In introducing the subject he made a point of its increasing usefulness, although there are many who are inclined to discount its value, and predicted that further experience, together with improvement in technique and apparatus, would increase its value still more. He gave a warning against too absolute a value being attached to the x-ray picture; the diagnosis was a personal matter, involving intimate knowledge of radiographic procedure and experience, combined with careful observation and interpretation of diverse signs. All radio-

graphic evidence should be considered together with, and in the light of, the clinical aspect of the case. Some reference was then made to the opaque meal, its composition and method of administration, and, following that, a description of the anatomy and radiographic appearances of the normal stomach. It was made clear that there is more than one type of stomach, and that the normal varies within moderately wide limits, and to a large extent in conformity with the general type of the individual. Then various points were dealt with which have to be considered in estimating the normal or abnormal condition of any stomach: these are its position, form, size, outline, tone, mobility, peristalsis, and motility, and they were described and considered in detail, and reference was made to circumstances which influence them. Dr. Prowse then turned to the particular consideration of some abnormal conditions. He referred first to gastroptosis, and deprecated its being looked upon as a pathological entity. It was an abnormal condition, not necessarily of itself giving rise to definite symptoms, but generally associated with, or secondary to, other conditions—especially organic lesions of an obstructive kind, though a number of cases appeared to be of mechanical, or possibly developmental, origin—or secondary to conditions of general health and chronic functional disturbance of the digestive organs. Gastric ulcer was then dealt with. He said that there were four classes: (1) superficial erosions, (2) penetrating ulcers, (3) perforating ulcers, (4) carcinomatous ulcers. The first were the most difficult to demonstrate, because they do not give rise to direct signs. The direct signs of ulcer were the barium-filled ulcer crater, and its accessory pocket, when perforating. The indirect signs included the various forms of spasm, from the incisura to hour-glass contraction, organic hour-glass, undue retention of food, alterations in peristalsis and tone (hypotonus), lessened mobility, and other minor signs. These were all considered in detail, together with their significance. The indirect signs were practically pathognomonic; the indirect required very careful interpretation and weighing in conjunction with the clinical evidence. Dr. Prowse then spoke of gastric cancer. X-ray diagnosis of this disease was of prime importance; the majority of gastric cancers gave radiological evidence of their presence, of their situation, and very largely of their extent. The most important sign of gastric cancer was alteration of contour, or filling defect; this must be fixed and permanent. Other signs were alterations in capacity of the stomach, diminished flexibility of stomach wall, patency or obstruction of the pylorus, changes of peristalsis, and alterations in motility of gastric contents. Finally, duodenal ulcer was dealt with. After a brief description of the anatomy and radiographic appearances of the duodenum, the irregularities which might be present in abnormal conditions were indicated. These affected outline, especially that of the first part of the duodenum, motility, and peristalsis. The signs of duodenal ulcer, like those of gastric ulcer, were (1) direct and (2) indirect. The only direct sign was deformity of outline; this was of various types, but the one essential characteristic of them all was persistence throughout examination. The indirect signs of duodenal ulcer were found in the stomach, and were concerned with changes in tone, peristalsis, and motility; gastric spasm might also be present. All these signs were described and considered in detail and their significance indicated. One combination of indirect signs was almost pathognomonic of duodenal ulcer—namely, hyperperistalsis associated with normal outline, though perhaps increased capacity of the stomach and undue retention of food. The paper was illustrated by lantern slides and reports of cases.

Dr. DONALD HALL showed a lad, aged 19, suffering from general paralysis of the insane and locomotor ataxy. The patient was the fifth of nine children, seven of whom were alive, the last two having been born dead. His father had tabes dorsalis and had been blind for nine years. The only stigma of congenital syphilis in the patient was a sunken bridge to the nose. He had had difficulty in walking for several months, and more recently his mother said he had become "nasty-tempered" and untidy in his habits. Clinically he showed gross ataxy of all four limbs, inactive pupils, absence of Achilles jerks, the knee-jerks still being present although diminished, double extensor response, tremor of face and tongue, characteristic speech, and mental enfeeblement. That day he had had a severe gastric crisis. Dr. H. M. GALT reported that the Wassermann test was +++ both in blood and in cerebro-spinal fluid; the gold test was positive, and cells in the cerebro-spinal fluid were 35 per cubic millimetre.

Reviews.

RESPIRATION.

UNDER the simple and inclusive title *Respiration* Dr. J. S. HALDANE of Oxford has published his Silliman Memorial Lectures at Yale University. Not only does the volume contain an excellent exposition of the subject of respiration by a worker who has long been regarded as one of the greatest living authorities in this field, but it is stamped throughout with the author's personality, and is one of the most peculiarly individual books that has ever been published on a purely physiological theme. It is in the main a development of a smaller book also published by the Yale University Press in 1917 under the title, *Organism and Environment as illustrated by the Physiology of Breathing*, in which Haldane dealt with the more general conclusions to which his life-long investigation of the problem had led him. The special merit of the volume now under review lies in the fact that it is no mere compilation and critical discussion of previous work, but is a fresh and original attack on a most interesting and, from a medical point of view, highly important problem.

The whole atmosphere of the book carries one back to a previous generation when authors did not fear to discuss their results and deductions in a broad philosophic way, not merely in relation to the organs and tissues examined, but to the organism as a whole and to its place in the scheme of Nature. To quote from the preface: "The time has come for a far more clear realization of what life implies. The bondage of biology to the physical sciences has lasted more than half a century. It is now time for biology to take her rightful place as an exact independent science: to speak her own language and not that of other sciences." But Dr. Haldane does not content himself with what many may regard as mere quixotic tilting at a frigid mechanistic conception of life, at the well-nigh ridiculous position taken up by many workers obsessed by the so-called facts of chemistry and physics; he has made a real and successful attempt to bring physiology and medicine into closer communion.

He opens with an historical introduction in which, in the space of fourteen pages, he gives a succinct and most readable account of the development of the subject from the time of Boyle and Mayow up to modern times. Room, however, might have been found for reference here to the interesting and ingenious work of Crawford, who claimed, with perhaps a certain amount of justification, that he had anticipated the discoveries of Lavoisier. This is followed by a couple of chapters on the regulation of breathing, where both the chemical and nervous control are fully dealt with. The discussion of the Hering-Breuer reflex in relation to "shortness of breath" in many nervous cases is very interesting. It may surprise some readers to learn that the respiratory centre so often referred to has not been anatomically determined and that the exact meaning to be attached to the term is still doubtful. Two chapters are devoted to the blood as a carrier of oxygen and of carbon dioxide. Although varying composition and concentration of the salts contained in the blood may account for varying dissociation curves of the oxyhaemoglobin in whole blood, the author maintains there can be no escape from the conclusion "that in different individuals of the same species as well as in different species the haemoglobin molecules are different."

In two more chapters Dr. Haldane discusses in detail the effects of oxygen want and the causes of anoxaemia. Both of these chapters are full of material of first-class clinical value. He believes that anoxaemia is frequently present in disease, but is seldom recognized. A detailed account of the methods of treatment of the condition of anoxaemia is also given. He writes here, "If there were only one clinical lesson derived from a perusal of this book I hope it would be that anoxaemia is a very serious condition." The important question of the relation of the reaction of the blood to respiration is discussed in Chapter VIII. The general conclusion reached is that the regulation of breathing in man during rest, under normal conditions, is regulation of the blood reaction. The actual changes involved are, of course, very small; so small indeed that, as the author says, "one might as well try to cut delicate histological sections with a blunt carving knife as try to demonstrate ordinary very minute changes in blood reaction

by the existing physical and chemical methods." Acidosis and alkali reserve are also discussed here in detail.

In Chapter IX the problem with which Haldane's name has so long been associated—namely, gas secretion in the lungs—is dealt with. There is a very clear statement of his own views and a fair criticism of those who do not accept his explanations. He adheres to his position in no unmislatable terms. "All the facts, therefore, and not merely our direct measurements, go towards showing that oxygen secretion is a most important physiological factor, not merely under exceptional circumstances, but during ordinary life at sea level." He has a very pretty jibe at the so-called purely objective methods at the end of this chapter. The next is devoted to the relation of blood circulation to breathing. It is maintained that the general circulation is correlated with the gas pressure in the capillaries, and hence it is neither the heart nor the bulbous nervous centres which govern the circulation rate, but the tissues as a whole. The regulation is as accurate and delicate as is the case in breathing. The conditions grouped together under the title "shock" are here discussed.

In Chapter XI the influence of the more commonly occurring impurities in air are examined—lighting gas, blackdamp, afterdamp, smoke, dust, etc. Many practical details in connexion with the industrial aspect of the problem are considered. Chapter XII deals with the effects of high atmospheric pressures and the practical applications of the observations made in special chambers for diving and caisson working; and Chapter XIII describes the effects of low atmospheric pressure, with special reference to mountain ascents and acronautics.

Dr. Haldane sums up his general conclusions in a final chapter which is undoubtedly one of the most original and stimulating in the whole book. It clearly states his position, it gives his philosophy, and it reveals a man who has the courage to face his facts and to interpret them in the light of his own experience and reason. "The universe is a spiritual universe, and not a dualistic universe of matter and mind."

The book, alas! is not provided with an index.

INFECTIONS OF THE HAND.

THE sum-total of disability and loss of wage-earning capacity resulting from whitlows and suppuration in the palmar spaces is so great, and the proper treatment is so often delayed, that a detailed study of *Infections of the Hand*,² such as that by Dr. ALLEN B. KANAVAL, should find very many readers; indeed, the book has already reached its fourth edition. Unfortunately the pages are a little overloaded with case records, and notwithstanding the thorough basis of anatomical and experimental demonstration, with commendable repetition of important points and a multiplicity of illustrations, the book is not an easy one to read, though it well repays even impatient study. The fact of the matter is that the number of possible paths and routes of extension for pus in fingers, palm, and forearm is great, and although the author's injection experiments seem to show definite paths, yet in practice the permutations and combinations of extension obscure the track. Nothing but good can result from memorizing the diagrams scattered over the pages; nothing but good can follow the employment of the sites for incisions indicated; and certainly much function in hand and fingers will be saved by following out the precepts for after-treatment in the chapter on exercise.

The author has a good deal to say about the prevalence of hand infections; yet, in the factories in which he investigated the cases, only about 20 per cent. of hand injuries became infected. Apparently about 6 to 10 per cent. of all industrial disability is due to hand infections. It is no wonder that he insists on the importance of early treatment of even the slightest scratches or abrasions. As a matter of fact, he found that the serious accidents rarely resulted in sepsis, because they necessitated immediate recourse to the doctor. An interesting point is brought out in reference to the relation between the prevalence of such an infection as tonsillitis and that of hand infections, which seem to follow much the same curve.

It would be a service to industrial surgery if a very small abstract of the volume under review—say, just the summaries at the end of each chapter or section, together with

the diagrammatic illustrations—were published as a pamphlet at a low price.

Dr. Kanaval's book itself deserves to be widely known to the medical profession.

A MANUAL OF ANATOMY.

A Manual of Practical Anatomy,³ by Professor WALMSLEY of Belfast, is the latest addition to the number of books designed to serve the student as a guide in the dissecting room. Considering how old are the study of anatomy and the practice of dissection it is somewhat surprising that there should be room for so many textbooks dealing with these subjects. The explanation, we believe, is that a considerable difference of opinion exists, not as to the facts of anatomy or the advisability, not to say necessity, of dissecting, but as to how much assistance it is desirable to give a student, how best that assistance can be given, and, lastly, how much a student is able to learn and retain in the limited time at his disposal. Each teacher has his own views, although probably these would not be so divergent were the curriculum longer and the mental capacity of the student a more constant quantity. Professor Walmsley appears to us to have adopted on these questions a very fair and judicious attitude. He appreciates the danger of giving too much assistance, and impresses upon the student the wisdom of making his own dissections and observations, encouraging him to that end by the provision of most explicit instructions and by withholding from him those elaborate and artistic illustrations which so sorely tempt him to dispense with the labour of dissecting. The illustrations are in the main simple line drawings, which give the conscientious student all the assistance he requires. We consider Professor Walmsley has succeeded in his aim to a noteworthy degree, and we can assure any student who works steadily through these volumes that he will acquire a thorough and sufficient knowledge of the main facts of anatomy, and this in a way which is more likely than any other to ensure remembrance.

The subject scarcely lends itself to originality in the method of its presentation, but whenever an opportunity occurs of breaking away from tradition the author is not slow to take advantage of it, as, for example, in the illustrations of the dissection of the lesser sac of the peritoneum and in the schematic figures showing the anatomy of the perineum—always a difficult region for the student to understand. A further extension of such examples may be suggested in view of the likelihood of later editions, for there is a tendency among writers of such textbooks to present the anatomy of the various regions always from the same point of view and to appraise too lightly the simple schematic figure as a help to the student.

The text and illustrations of the *Manual* under review attain a high standard of accuracy and of interest, and we have no hesitation in warmly commending it to the student as a thoroughly sound and trustworthy work which provides him with all that he is ever likely to require either in the examination room or in the course of his future career as a medical practitioner.

CHLOROFORM ANAESTHESIA.

THE aim of Dr. GOODMAN LEVY in writing his book on *Chloroform Anaesthesia*⁴ is to bring that method into close touch with the experimental sciences. He treats very fully of chloroform from the points of view of its physical properties, its physiology, its pharmacology, its pathology, the onset of asphyxia, its absorption and elimination, methods of administration, and delayed poisoning resulting from it.

The book thus goes deeper into fundamentals than is usual in a merely practical treatise, and will on this account be welcomed by all anaesthetists who are interested in the sciences which have made possible their technical skill in administration. That most of the alarming symptoms that may be met with in the course of the administration of

³ *A Manual of Practical Anatomy*. In three parts. By T. Walmsley. Part I. The Upper and Lower Limbs. Part II. The Thorax and Abdomen. Part III. The Head and Neck. London: Longmans, Green, and Co. 1920-21-22. (Demy 8vo. Part I, pp. 176; 59 figures; 9s. net. Part II, pp. 233; 82 figures; 10s. 6d. net. Part III, pp. 272; 96 figures; 10s. 6d. net.)

⁴ *Chloroform Anaesthesia*. By A. Goodman Levy, M.D., M.R.C.P. With a foreword by A. R. Cushny, M.D., LL.D., F.R.S. London: J. Bale, Sons and Danielsson, Ltd. 1922. (Demy 8vo, pp. viii + 159; 9 figures. 7s. 6d. net.)

² *Infections of the Hand*. By Allen B. Kanaval, M.D. Fourth edition. Philadelphia and New York: Lea and Febiger. (Med. 8vo, pp. xlii + 500; 185 figures. 5.50 dollars.)

chloroform occur in the early stages of anaesthesia is common knowledge, and therefore the author's statement that when chloroform is administered by a careful anaesthetist danger lies more in under- than in over-dosage will not cause surprise. The grounds on which the statement rests are fully gone into. Ventricular irritability is most marked under light, and least under deep, anaesthesia. There is little experimental evidence that cardiac inhibition has anything to do with cardiac syncope, and it is by no means clear that sudden death under chloroform is due to depressive action of the drug on the vasomotor centres. Some other explanation must be found, and the most probable is the onset of ventricular fibrillation. To produce the various forms of stimulation known to lead to ventricular extra-systoles under chloroform anaesthesia the narcosis must be light; they are difficult to evoke, and have never been known to progress to the usually fatal condition of ventricular fibrillation, when anaesthesia is deep. The human subject can recover from a first and even, though rarely, from a second attack of ventricular fibrillation, but the condition is extremely grave and can best be avoided by giving a sufficiently concentrated vapour from the very commencement of the chloroform induction. Administration must be regular as well as sufficient in vapour strength, and, if struggling occurs, the administration should be continued and the vapour strength increased, but the opposite course is commonly taught. We suspect that medical anaesthetists may perhaps have some lessons to learn from veterinarians; we understand that in horses a very stiff dose is safer and is habitually used, whereas in dogs and cats the strength of the vapour must be low.

Dr. Levy's book deserves recommendation, even though it does not settle the controversy as to the indications for chloroform and ether respectively. There are still certain cases in which chloroform is clearly indicated as the drug of choice; but if there must be a routine anaesthetic, then ether is to be preferred until some other anaesthetic that can be said to be ideal in every case has established its reputation.

HEALTH SERVICE IN INDUSTRY.

In his book on *Health Service in Industry*⁵ Dr. W. IRVING CLARK, Junr., gives a very clear and succinct account of the best methods for investigating and improving the health of the workers in factories. He describes what may be regarded as almost an ideal system, which is necessarily somewhat expensive, but such a system is in actual operation in many large American factories. Dr. Clark suggests that in a factory of 3,000 workers there should be one full-time doctor, two part-time doctors, and three nurses. Part-time dentists and ophthalmic surgeons should also be available. He estimates that a service such as this, with the necessary equipment of dispensaries and medical supplies, would cost about 6 dollars a year per worker; he states that in actual practice a number of factories have been found to expend about 5 dollars, though in some establishments it reached 11 dollars.

And what is the return for this considerable outlay? So far as estimates can go it is more than equivalent to it. First, each applicant for work is submitted to a thorough medical examination, including tests for all the principal joints in the body, and he is graded in one of four classes, according to his health and strength. Thereby the firm is enabled to select suitable applicants for various kinds of work, and to reduce its labour turnover, which is always a very expensive item. Periodical examination of the employees, coupled with inquiries into cases of sickness and accident, and proper treatment of any injuries incurred during work, reduce the time lost from sickness and the expense of compensation. Maintenance of the best conditions of lighting, heating, ventilation, and sanitation in the factory not only directly promotes the health and efficiency of the workers, but it increases their goodwill and contentment, and constitutes a bond between employers and employees. These and other advantages secured by a complete medical service are undeniably of enormous value to the workers, and it is to be hoped that in course of time they will become available in all the large factories of this country; but alas, in how many do we find them at the present day?

An elaborate medical service is impossible in small factories, which, after all, constitute the majority of the industrial establishments in this country and in America. Dr. Clark

points out that in them most of the service suggested can be carried out by means of a part-time doctor, backed up by a trained assistant from the ranks of the factory workers. In a factory of 1,000 workers a full-time nurse should be employed, for, in addition to the treatment of minor injuries and cases of sickness, she should be made responsible for maintaining accurate records. For this purpose a number of suitable forms and tables of directions are given by Dr. Clark. In fact, his book is full of practical details which could only have been collected as the result of long personal experience. On every ground, therefore, it is cordially recommended to everyone interested in the welfare of our industrial classes.

A GUIDE TO INSURANCE MEDICAL PRACTICE.

Insurance practitioners, by their want of acquaintance with the regulations which govern medical benefit under the Insurance Acts, sometimes throw a great deal of unnecessary work on the shoulders of those who assist in administering the Acts, and especially upon the members of their own Panel Committees and Medical Service Subcommittees.

The ordinary busy doctor may grudge the time and often has not the inclination to refer to the official regulations when in doubt as to his duties, nor does the legal terminology of these documents offer him any attraction to do so. Consequently he will welcome *Medical Insurance Practice*⁶ as a handy reference book, giving a concise yet readable interpretation of the National Health Insurance Acts and regulations, with an authority which, though not claiming to be official, is based on information obtained at the Ministry of Health.

The scope of the work undertaken by Mr. R. W. HARRIS and Mr. L. S. SACK may best be indicated by a brief summary of its contents. The first chapter gives an introductory sketch of the general field of insurance practice and of the relationship of the medical man towards the insured person. The second chapter describes the responsible authorities and the relationship of the practitioner towards them; the third and fourth chapters deal respectively with insured persons for whose treatment the practitioner is primarily responsible, and those who are on other doctors' lists. Chapters V and VI explain the limitation of doctors' lists, and the position in regard to deputies, assistants, and partners. The four following chapters deal with the nature and scope of medical treatment and attendance; prescribing and the supply of drugs and appliances; certificates of incapacity, and records of illness. The relation between practitioners and the regional medical staff is discussed in Chapter XI. Four chapters are devoted to remuneration, and three to complaints, appeals, and disciplinary action. The last two chapters treat of withdrawal from insurance practice, the transfer of practices, and some miscellaneous matters. The appendices give extracts from official documents, and there is a comprehensive index.

Prefaces commending the work to insurance practitioners at large or to particular groups of practitioners are contributed by Dr. H. B. Brackenbury, Chairman of the Insurance Acts Committee; Dr. H. G. Dain, Chairman of the Conference of Local Medical and Panel Committees; Dr. H. J. Cardale, Chairman of the London Panel Committee; Dr. J. P. Williams-Freeman, Chairman of the Rural Practitioners' Subcommittee of the Insurance Acts Committee; and by Dr. J. R. Drever, Scottish Medical Secretary of the British Medical Association.

The authors are to be congratulated on the manner in which they have accomplished their object, and insurance practitioners will find this handbook very helpful. The chapters relating to the issue of certificates and charging fees to insured patients may be quoted as good examples of clear information on points that are constantly being misunderstood by panel doctors. The information on transfer of practices in Chapter XIX does not seem to be quite clearly enunciated: the concession that the Insurance Acts Committee has so strongly urged upon the Ministry of Health has now been granted and a great grievance removed. We should like to see added in any future edition a clear statement of the practitioner's duty to an insured patient whose name is removed from his list as from some previous date.

We recommend Panel Committees to consider in their own interests how they may best bring this excellent work before the notice of their constituents.

THE ANNALS OF MEDICAL HISTORY.

THE portrait of William Hunter on the cover of the summer number of the *Annals of Medical History*⁷ illustrates Dr. Thomas McCrann's account of the two brothers, William and John, whom he compares, showing reason to regard William as not so much the inferior of his younger brother as is perhaps generally thought. This number is prefaced by the frontispiece of Jean Riouan's *Manual of Anatomy*, which also supplements an article with fine illustrations—that of Dr. F. R. Packard on Guy Patin and the medical profession in Paris in the seventeenth century. Guy Patin's fame must rest, so the editor is convinced, not so much on his professional writings as on his outspoken letters, which were published eleven years after his death and contain reflections on those in high places, including Richelieu and Mazarin. Dr. H. Viers gives an account of Cardinal Nicholas Cusaenus (1401-64), like Roger Bacon, a pro-Renaissance scientific scorner much in advance of his time, and reproduces a translation, provided by the late Sir William Osler, of his *De Staticis Experimentis*. The life and work of Louis Daniel Beauportligny, who, as was shown in these columns some years ago, may be considered to be the father of the doctrine of insect-borne disease, are sketched by Dr. Casey A. Wood, who spent the winter of 1920-21 in British Guiana within sight of Beauportligny's grave, and has therefore been enabled to verify some published statements, and to correct others, relating to this pioneer in the now established part played by the mosquito in the spread of disease. In a short but attractively written article on the treatment of convulsions (totany) with calcium in the seventeenth century, Dr. P. G. Shipley of Baltimore, who has done so much work on experimental rickets, relates how in the first year of the reign of William and Mary Dr. Walter Harris, their physician, treated empirically the disease afterwards known as totany with calcium salts according to the best science of his day. Sir Richard Blackmore, a voluminous writer of verse and prose, some of which was intended to counteract the gross licentiousness of the drama and poetic literature, and to reprove the wits for their immorality and irreligion, is now probably remembered chiefly for the revenge taken on him by Pope, Cowdington, Garth, and Steele. As a corrective to the general impression of Blackmore as a pompous and stupid pedant it is therefore well to have Dr. T. H. Toomoy's justification of this physician, based on original records unknown to his earlier biographers. His medical writings are described as suffering from a lumbering style, and as having not only omitted the aphorisms of the Fathers of Medicine but insisted on the necessity of Aesculapians being endowed with eyes to see and souls to comprehend. In his attractively written narrative "What was Kappa Lambda?" Dr. Channery D. Leake touches on the psychology of secret medical societies, and gives an account of "the Kappa Lambda Society of Aesculapius," founded by the idealistic Dr. Samuel Brown at Lexington in 1819 to improve the ethics and mutual relations of medical men; established with these high ideals and with branches scattered over North America it is sad to find that it came to grief within twenty years, not without acrimony and scandal. There is a short note on Benjamin Franklin's invention of bifocal spectacles in 1785; as usual the editorials provide interesting reading.

NOTES ON BOOKS.

IN *Difficulties: An Attempt to Help*⁸ Mr. SEYMOUR HICKS gives to young men advice expressed in the simple and friendly language that every father may use to his son. Too often, however, the British father, restrained by shyness and self-consciousness, fails to provide his son with the warnings that he knows are so sorely needed; indeed, to discuss intimate details with a boy "who has all the goodness of his mother's nature shining through his eyes is perhaps one of the most difficult tasks a father has to face"; it is for this reason that Mr. Seymour Hicks's series of seventeen talks, mainly addressed to boys about to leave school for their life's work, supply a definite want. The subject-matter covers the large field of the physiology of healthy life, religion, occupation, sport, gambling, personal finance, the choice of friends, reading and recreations, drink, marriage,

sexual matters, and blackmail. Throughout the kind and shrewd admonitions there runs the brightening thread of humour, which is happily described as a sixth sense—the greatest of our senses, and the motif of genial sympathy with the weakness of poor human nature. The care of the teeth with the use of dental silk and quarterly visits to the dentist is insisted on; smoking is permitted, but a number of wise cautions are appended, and on the whole it is held that were tobacco banished from the country it would be an advantage, though in that event "there would be fewer throat specialists and 'the lost chord' might never have been written." The chapter dealing with matters of sex, which was admittedly hard to write, is the most important of them all. Continence is first enjoined, with common sense recommendations on the value of physical fatigue as a help; then the results of venereal disease are sketched, and the necessity for preventive measures is emphasized though the details are not given, reference to Mr. H. M. Robson's book, *Sexual Disease and Protection*, and the publications of the Society for the Prevention of Venereal Disease being made for this purpose. The author has some very plain words on the vital importance of early skilled treatment being sought should infection be contracted. The medical details upon which Mr. Hicks ventures are correctly given, and we can commend the book as full of common sense and wise advice, all the more likely to be effective because expressed in an unconventional way.

Paraguay, among the South American States, is that probably of which the average Englishman knows least, which is saying a good deal. It was therefore with some expectation of instruction as well as amusement that we opened *The Golden River*,⁹ by Major J. W. HILLS, M.P., and IAN THE DUNBAR. We ought perhaps to have been warned by the name of the historian of fly fishing for trout that it would be a book mainly about fishing. The fish the party of four—two men and two women—went out to catch was the dorado, a big fish (several over 40 lb. were taken), a very sporting fish, fighting as gamely as the salmon, displaying similar tactics, and having a pink flesh very good to eat. It is not a salmon (it belongs to the Characidae); it does not go to the sea, and it is doubtful whether it migrates at all. Where it spawns is not known, but it has fifteen hundred miles of waterway from north to south and as much from east to west to choose from. Later on, when some of the party visited the Chaco, we hear a little of the birds of that great plain. None of the party seem to have been ill, though mosquitos were numerous, and sandflies in clouds found them as much of a treat as Paget, M.P. Mosquito bells by day and nets by night were essential, and one of the writers—a lady—praises citronella, by which is probably meant citronella oil, which has a considerable reputation for driving off mosquitos; it is sometimes mixed with carbolic acid. It is, we believe, desirable to get the oil made under the direction of the Ceylon Government. The book is well illustrated, mostly by photographs, but there are some pleasant pencil sketches in the text.

Professor S. LYLE CUMMINS has written in verse eight little plays for children.¹⁰ Each of the three volumes amongst which the plays are distributed is prefaced by excellent hints on how to produce children's plays; and the little books are made additionally attractive with illustrations by G. L. Stampa. The author evidently recognizes the innate strain of cruelty in children, and nearly all the subjects he has selected are of the blood-thirsty or blood-curdling variety. The blood-curdling effect is increased by some of the professor's descriptions, as in the remark of Bluebeard about the heads of his former wives in the chamber of horrors:

"And just to ensure that they always look nice—
I know 'tis expensive—I keep 'em . . . on ice."

We are not sure that Professor Cummins is wise in his "Forewords," and in sundry passages in the plays, in making cryptic allusions to current political topics. A modern juvenile Bluebeard may understand the couplet:

"In destroying poor Bluebeard you drive the last nail
In the coffin of 'power in the hands of the male.'"

Or the line:

"And the masculine dies at the hand of the male."

But, as the monso says to the Sleeping Beauty, "I don't think!"

CAUSES AND PREVENTION OF BLINDNESS.

FINAL REPORT OF THE COMMITTEE.

In September, 1920, Dr. Addison, then Minister of Health, set up a Committee "to investigate and report on the causes of blindness, including defective vision sufficient to impair economic efficiency, and to suggest measures which might be taken to prevent blindness." A Committee of fourteen was appointed, including the Right Hon. G. H. Roberts, M.P. (chairman), Dr. J. C. Bridge (Factory Department, Home Office), Dr. A. Eickholz (Board of Education), Mr. E. D. Macgregor (Ministry of Health), Mr. J. S. Nicholson (Ministry of Labour), Mr. G. F. Mowatt (National Institute for the Blind), Mrs. Wilton Phipps (London County Council), Mr. W. M. Stone (Scottish Board of Health), Dr. James Taylor, the neurologist, Mr. Bishop Harman, Dr. J. B. Lawford and Sir John Parsons, ophthalmic surgeons, and Mr. Stephen Walsh, a Labour M.P. Mr. C. J. Bond was added to the Committee in April, 1921. For the first year of the Committee's working the medical secretary was Dr. R. A. Farrar, who died in Russia recently "during the performance of duties finely and humanely inspired"; for the second year that office was undertaken by Dr. James Pearso of the Ministry of Health.

The Committee held forty-six meetings and numerous meetings of two subcommittees. Sixty-six witnesses were examined and special inquiries were made. An interim report was issued in 1921 relating to the light used in cinema studios; this was noticed at the time in our columns. The final report of the Committee is now issued, a concisely written octavo pamphlet of 136 pages.

The Number of the Blind.

The Register of the Blind for England and Wales, compiled by the Ministry of Health, shows that in 1921 there were 34,894 persons "too blind to perform work for which eyesight is essential." Males are slightly in excess of females; 8 per cent. are under the age of 16 years, 37 per cent. between 16 and 50 years, 34 per cent. from 50 to 70 years, and 20 per cent. over 70. The latest return of the age at which persons become blind shows that 21 per cent. become blind within the first year of life, and thereafter about 10 per cent. for each decade up to 70 years.

THE CAUSES OF BLINDNESS.

In this section figures are given from several returns of blind infants, children, and adults. The chief returns are those published by Mr. Bishop Harman, which cover figures under each of these heads, including the large volume of figures which he has collected from the blind schools of the London County Council; other returns have been collected by special inquiries made for the Committee by the Board of Education, and by Mr. P. G. Doyné of London, Mr. H. R. Bickerton of Liverpool, and Dr. A. Fells of Bristol. From these several sources there is obtained a fair appreciation of the relative incidence of the several causes of blindness, and thereon the report considers them seriatim. The order given is as follows: ophthalmia neonatorum, syphilis, congenital malformations, surface inflammations in childhood, trachoma, myopia, glaucoma, industrial disease and accident, eye accidents in civil life, blindness due to the war, sympathetic ophthalmia.

Ophthalmia Neonatorum.

The incidence of blindness due to this disease varies according to the age at which the inquiry is made. In infants the incidence is as high as 49.2 per cent., in school children between 20 and 28 per cent., and in adults it falls as low as 3 per cent. It is evident that this disease is a very serious factor in the causation of blindness, and constitutes a problem of vital national importance, the more especially as an individual blinded is affected from birth and throughout the years of highest economic efficiency. The incidence of the disease appears from statistics to vary considerably in different districts. It is low in counties—less than 10 per 1,000 births; it is high in county boroughs, in which the rates vary exceedingly. The variations are so marked that they appear to indicate differences in conditions notified rather than actual differences in the prevalence of the disease. Accordingly there is some hesitance in making deductions from the figures; but so far as this is allowable it appears that there is no diminution in the incidence of the disease notified, but rather

material increase, since the year 1918. It is, however, considered that notification does serve its main purpose—that of enabling cases to be brought under early and efficient treatment; for, whilst there is a higher rate of notification, there is definite evidence that blindness due to the disease is lessening. The report states:

"We have, however, clear indication, from figures submitted to us by Mr. Bishop Harman with regard to school children in London, that the proportionate incidence of blindness due to this disease has markedly decreased. These figures show that between 1907 and 1913 inclusive there were admitted to schools for the blind 737 children, of whom 134 were blind from ophthalmia neonatorum, or 18.03 per cent. The number admitted between 1914 and 1920 was 755, with 89 blind from the disease, or 11.91 per cent., a very material diminution. Again, if the figure for the first period of 134 children blind from the disease be related to the average roll over the elementary school roll in London over blindness from this cause in 18.3 per figure 89 of the second series be related to the average roll over the years 1914-20 the incidence is 12.5 per 100,000."

Despite this definite evidence of a diminution in the cases of blindness from ophthalmia neonatorum, the Committee is not satisfied with conditions as they exist. It emphasizes the necessity for the prevention of the disease by combating gonorrhoea, which is mainly responsible for the severe inflammations which may result in blindness. This is a matter engaging the attention of the Ministry of Health in dealing with the prevention and treatment of venereal disease in general. The next line of defence is the treatment of the expectant mother. The report says:

"It is gratifying to note that we owe to an Englishman, Benjamin Gibson of Manchester, who wrote in the year 1807, the first clearly reasoned description of the rational means for preventing ophthalmia neonatorum. It is difficult to believe that his words, which are quoted below, could be bettered even at the present day. They were as follows: 'First to remove, if possible, the disease in the mothers during pregnancy; second, if that cannot be accomplished, to remove artificially as much of the discharge as possible from the vagina at the time of delivery; and third, to pay at all events particular attention to the eyes of the child by washing them immediately after delivery with a liquid calculated to remove the offending matter or to prevent its noxious action.'"

The more general adoption of clinical investigation during pregnancy should lead to early discovery of cases of vaginal discharge, research into its bacteriology, and prompt measures for securing treatment by a private practitioner, at a general hospital, at a special session of an ante-natal clinic, or at a venereal disease clinic.

Prophylaxis at birth is now very generally adopted. The detailed care of the eyes of the newborn has been the subject of special attention by the Central Midwives Board. If the rules of the Board were carried out universally there is little doubt that ophthalmia neonatorum occurring in the practice of midwives would be materially reduced. It does not appear to the Committee that the average practising midwife is, as a rule, either suitably trained or equipped for this purpose. Six months' training is insufficient, especially when it is found that the standard of general education of candidates is so low that "many pupil midwives who present themselves for examination have not had sufficient education to enable them to express themselves on paper and have to be examined *viva voce*." Further, there is no security that a midwife will ever have seen a case of ophthalmia neonatorum before being placed on the register. The Committee recommends:

"... be made for pupil midwives to visit ophthalmic departments of general hospitals, so as to gain direct experience of ophthalmia neonatorum."

Considering the use of prophylactic drugs, the Committee is fully satisfied as to the efficacy of Credé's method in skilled hands, but cannot recommend it for routine adoption by midwives. There is risk that they may think this is all that is necessary and neglect the scrupulous cleansing, which is even more important, or mistake as "only a little reactionary discharge" what is really a manifestation of the disease itself. The report adds:

"We consider, however, that Credé's method should be used under medical supervision in all cases where vaginal discharge is known to exist. Where such prophylactic method is adopted, we consider nitrate of silver to be the most effective agent, but that it should not be used in stronger solution than 1 per cent."

The Committee considers it of paramount importance that the disease should be diagnosed and notified at the earliest possible moment in order that nursing facilities may be available or provision made for admission to hospital. It thinks that if medical practitioners had facilities provided for

consultation with an ophthalmic surgeon at the home of the patient, and for prompt bacteriological investigation, there should be less delay in the proper treatment of the disease, and it recommends accordingly. Under the Notification Births Act, 1915, visits of health visitors have been of great assistance; no less than 93.5 per cent. of the cases of ophthalmia neonatorum occurring in 1919 were so visited. Arrangements for home nursing have been made in most metropolitan and county boroughs—that is, the areas in which the disease most frequently occurs. But the Committee is not satisfied that the arrangements are always sufficient.

"Ophthalmia neonatorum is emphatically a disease which requires skill and experience in nursing, and, if the case is to be successfully treated at home, skilled nursing should be available from the earliest possible date." The midwife is inadequate for the purpose. "Irrigation by a trained nurse must be carried out at frequent intervals, both by day and by night, if the sight is to be saved."

The Committee recommends that the Ministry of Health should take steps to ensure that adequate nursing provision is always available for cases of ophthalmia neonatorum which are not admitted to hospital.

The Committee found evidence that some medical practitioners failed to recognize early and notify promptly cases of the disease. It considers that the inadequate knowledge of the diseases of the eye possessed by the large majority of medical practitioners on admission to the Register is in a large measure due to the very limited amount of training in this subject which they receive as medical students, and the common absence of any examination in the subject for qualification. It therefore recommends that "the General Medical Council again be urged to insist that every student presenting himself for a qualifying examination in medicine shall be examined in ophthalmology."

Speaking generally, it is found that in London and large cities and in many county boroughs provision is made for hospital accommodation both for babies and their mothers, and in some towns and in many rural areas there is no such provision. Examining special arrangements made for these cases, it is considered preferable that hospital accommodation should be provided by securing beds in a few of the well-known teaching hospitals in centres convenient to the great masses of the population, rather than in special hospitals provided for the purpose as has been tried in London. There would be the advantage in the use of general hospitals in that students attending the practice of these hospitals would become familiar with the care and treatment of these cases, which they would not so readily do if provision were made at a special hospital alone. Also it is found that a special hospital soon becomes stigmatized and mothers are unwilling to enter. The report adds that—

in a few places cases of ophthalmia neonatorum are treated in hospitals for infectious diseases. In our opinion it is not desirable to expose mothers during the puerperium or their infants to even remote risk of infection."

Syphilis.

Syphilis, both congenital and in the acquired form, is responsible for a large amount of blindness. It causes interstitial keratitis, iridocyclitis, choroiditis, and optic atrophy. In children the incidence of blindness from this cause may reach as high as 31.4 per cent. The figure is less when with added years other factors producing blindness come into play; but—

considering the information available to us we think it would be correct to estimate that syphilis is the direct cause of not less than from 10 to 15 per cent. of the blindness at present existing in this country. This is an alarming figure, and it is to be remembered that many other cases of blindness are due to disease consequent on vascular disease possibly cannot be accounted for in the statistics. . . . but part of the wide problem of the menace of syphilitic disease in general. Its diminution will depend upon the success of the various measures—moral, social, medical—directed against the evil. It is to these measures that we must turn over from this time. Patients too readily relinquish treatment after the first abatement of symptoms, and consequently develop later manifestations, including affections of the eye, which would have been prevented by persistent treatment."

Congenital Malformation of the Eye.

Cataract, dislocation of the lens, absence of iris, and albinism account for a considerable amount of blindness in school children, varying from 20 to 30 per cent. Certain defects

occur in families, but the majority appear sporadically. Knowledge is not at present available to enable the indication of prophylactic measures for these conditions, except that where an inherited tendency is manifest marriage and parenthood are undesirable.

Surface Inflammations in Childhood.

The exanthemata, measles particularly, take a toll of infant eyesight. These cases account for from 3 to 5 per cent. of blindness in school children. Phlyctenular keratitis and chronic blepharitis also do much damage, the keratitis alone being responsible for another 3 per cent. of blindness in school children. Poor districts are particularly liable to these diseases. Dr. P. J. Hay of Sheffield showed that in the good districts only 6 per 10,000 of the children were affected by blepharitis, whereas in the bad districts the rate was as high as 26 per 10,000. The actual blinded eyes form only a small proportion of the injury done by the inflammations. For the prevention of these diseases attention must be directed primarily to improvements in diet, housing, sanitation and ventilation, and in personal cleanliness; for treatment the provision of special institutional accommodation, such as that recently arranged in London between the school authorities and the Metropolitan Asylums Board, is essential; the provision is at present inadequate. Some difficulty arises in the treatment of these chronic cases where parents are of the more ignorant sort. They will not allow their children to remain under treatment for a sufficient time to effect a cure. The powers of the "Children's Act" are insufficient to effect the purpose, and the Committee recommends:

"That the Board of Education should consider the question of seeking additional powers to enable a local educational authority to require a parent to submit a child suspected to be suffering from chronic external eye disease to medical inspection and adequate medical treatment where the authority deem such inspection and treatment necessary."

Trachoma.

This disease, once so terrible in this country, and still disastrous in causing blindness in other countries, is now rare here. Out of 1,855 school children only 4, or 0.21 per cent., owed their condition to the disease; and out of 601 blind of all ages 8, or 1.3 per cent. The main necessity is to ensure that the disease shall not be reintroduced into this country by unguarded alien immigration. The Committee inquired into the arrangements for the examination of immigrants, and considered that the Aliens Acts, which formerly provided many loopholes by which aliens suffering from the disease might enter the country, are now so administered as on the whole to deal adequately with the risk. It recommends, however,

"That in sanctioning appointments as medical inspectors under the Aliens Acts, the Ministry of Health should endeavour, as far as possible, to secure that such officers, if they have not already had special experience of contagious eye diseases, and particularly of trachoma, should be afforded the opportunity of acquiring it."

Reference is made to the singularly effective measures taken in France during the war, under the superintendence of Sir William Lister, to stamp out trachoma amongst the labour corps imported from Egypt and China. The earliest recruits were badly affected, later companies were selected at the port of embarkation, so that the incidence was much lower. Measures taken to separate the affected men had the most beneficial results. The whole incident forms a striking illustration of the value of preventive medicine. The application to civil life is obvious.

Myopia.

Actual blindness due to degeneration of the eyes from the effects of myopia accounts for some 3 to 6 per cent. of blindness in school children, and up to 14 per cent. amongst blind persons of all ages. It is also responsible for a serious amount of impairment of vision short of actual blindness. In a series of 3,500 blind and partly blind children collected by Harman in London, besides 54 quite blind there were 1,191 cases of myopia of a degree sufficient to necessitate education in special myope classes. The majority of the children had myopia of over 10 diopters. It is obvious that even when provided with suitable glasses these children see with difficulty. Further, there is evidence that these eyes are frail, and there is over-present risk of damage to or degeneration of the retina, and this risk is increased by strain. The Committee reports very favourably on the work of the

myope classes first instituted in London in 1908, and since adopted in many towns in this country and abroad; and it recommends:

"That further provision should be made by education authorities for the education in myope classes or by similar methods of children with serious defect of vision requiring such facilities, and that steps should be taken to discover these cases at such an early age as will allow of preventive measures being adopted."

Reference is given to Harman's recent evidence of the risk of breakdown and inefficiency in work, of myopes engaged in habitual close eye work. Taking cases of myopia above 3 D. of ages from 20 to 60 years the myopes who habitually did close work had 53 per cent. of failures, as against 9.4 per cent. amongst myopes who did no continuous close work. It is therefore considered that every encouragement and assistance should be given to children's after-care committees and juvenile employment committees in the selection of suitable occupations for those short-sighted children. A classification of suitable occupations is given based on London experience.

Glaucoma.

The incidence of blindness due to this disease varies from 9.15 per cent. for a group of blind of all ages to 29 per cent. in a home for the aged blind. The determining cause of primary glaucoma is unknown and therefore unpreventable. Blindness can be obviated by early and adequate treatment. It is essential to emphasize that in the early stages glaucoma may appear to be relieved by the frequent change of glasses; and in this connexion the Committee draws attention to the grave risk which arises from the treatment of these cases by opticians who are not qualified to detect the real condition. The difficulty of and the necessity for prompt recognition of acute and chronic glaucoma also give added weight to the recommendation for more thorough training of the medical student in ophthalmology. The general practitioner sees such cases first. The acute form may be mistaken for iritis, with disastrous results if it be treated as such; the headache and vomiting may suggest a bilious attack, to the overlooking of the eye condition. The chronic form is so insidious in its onset that it may easily be overlooked. Hence the necessity for trained and alert practitioners.

(To be continued.)

THE HISTORY OF TUBERCULOSIS.

SCHORSTEIN LECTURE.

The Schorstein Memorial Lecture was delivered by Dr. Penex Kinn at the London Hospital Medical College on November 8th. The title was "Forty years in the history of tuberculosis," but the lecturer traced the earlier history also.

Early History.

Dr. Kidd said that forty years ago, when the tubercle bacillus was discovered, there was a distinct parting of the ways in the history of tuberculosis. The malady had attracted attention as far back as the time of Hippocrates, who held that phthisis was an ulceration of the lungs. Hippocrates made no mention of consumption as being contagious, but Aristotle expressly said that it was, and Galen regarded consumptives as dangerous persons to live with. No real advance in the knowledge of phthisis took place until the seventeenth century, when Sylvius recognized the existence of lymph nodes or tubercles in the lung, which he regarded as enlarged glands, the enlargement being the result of an accumulation of viscid humours or secretions. Richard Morton, later in the century, embraced Sylvius's views with regard to the glandular origin of tuberculosis, but insisted upon the frequency with which healing took place. Thomas Willis, a contemporary, was the first to controvert the prevailing belief that phthisis invariably depended upon an ulceration of the lungs; he had made autopsies on persons who had died from the disease, and found the lungs free from ulceration. Desault, a Frenchman, compared tubercle in the lungs with the condition of scrofula, and attributed contagion to the presence of worms—a remarkable foreshadowing of the parasitic theory of disease. William Stark, who died in 1770, furnished an excellent anatomical description of a tuberculous lung. Towards the end of the eighteenth century Nathaniel Baillie, physician to St. George's Hospital, gave a complete description of the pulmonary lesions in consumption, such as could hardly be bettered to-day. It was interesting to trace the persistence of the Hippocratic notion, despite the knowledge that phthisis might occur without any ulceration of the lung. The existence of tubercles in organs other than the lungs did not escape Baillie's observation, but he failed to see any connexion.

The Nineteenth Century.

The nineteenth century marked much greater progress. Among the first of the great workers was Bayle, who traced the coexistence of tubercles in various organs to a common cause, and who gave the name of tuberculosis to the disease. But a greater than Bayle was at hand to throw light in the darkness. In 1819 Laënnec published his memorable work, *Traité de l'auscultation médiate et des maladies des poumons et du coeur*, which revolutionized the theory of consumption and the clinical treatment of tuberculosis. He declared that all phthisis was tuberculous in character, and that tubercles might arise in any organ, and were connected by a special disposition or diathesis. Laënnec's chief claim to immortality rested upon his mediate auscultation, but his pathological study of consumption alone would entitle him to be regarded as one of the great pioneers of medicine. His views did not find universal assent, and in Germany Virchow insisted that the caseous change was not characteristic of tubercle, and that a similar change occurred in new growths unrelated to tubercle. The promulgation of these views let loose a flood of controversy, especially in Germany, and foremost among Virchow's supporters was Niemeyer, who applied his master's doctrine in a most uncompromising manner. In 1865 Villemin announced his discovery that tuberculosis was a specific affection; its cause residing in an inoculable agent, and that it belonged to the class of virulent maladies. It was not surprising that Villemin's conclusions should have been contested. Attempts were made to show that tuberculosis could be induced in animals by inoculation of non-tuberculous material, but further experiments under stricter conditions only served to demonstrate the truth of Villemin's hypothesis. William Budd came to the conclusion that tuberculosis was a zymotic and infectious disease like scarlet fever; but it was long before the doctrine of infection found general acceptance.

Discovery of the Bacillus.

It came, therefore, more or less as a revolution in the medical world when, in 1882, Robert Koch announced his discovery of the tubercle bacillus—a discovery which completely revolutionized the views of the profession both as to diagnosis and treatment. Before long the identity of human and bovine tuberculosis came to be generally accepted. Professor Bulloch had stated that between 1882 and 1900 very few seriously doubted that human and bovine tuberculosis were identical, though dissentient voices were raised here and there. In 1901 Koch declared that they were not identical. As a result of extensive experiments on young cattle inoculated in various ways he convinced himself that human tuberculosis could not be communicated to cattle, whereas in animals infected with bovine tubercle bacilli general tuberculosis of the bovine type usually resulted. Obviously the question of the infection of man with bovine tuberculosis could not be satisfactorily settled, but Koch considered such infection improbable. These statements stimulated much experimental work, and Koch's conclusions were challenged. Some investigators thought that the morphological and cultural distinctions characterizing the two types were well marked, others that the differences were unimportant. It seemed now to be established that Koch was right in stating that human and bovine tuberculosis were not the same disease; that there were pathogenic differences could not be doubted. In the course of his researches Koch discovered that tuberculous animals were very sensitive to extracts of the cultures of the tubercle bacillus, the result being a febrile illness combined with inflammatory and necrotic changes in the tuberculous foci. He was led to apply tuberculin to diagnosis and treatment, and the result of his experiments on cattle showed the tuberculin test to be trustworthy for diagnosis. In the case of the human being the question could not be settled so simply. In some instances of severe progressive tuberculosis no reaction occurred, and a negative reaction was found in some tuberculous persons suffering from typhoid fever or other specific diseases and in pregnant women. Objections had been raised to the specific diagnostic value of tuberculin, and clinicians had come to discount its value. Von Pirquet's cutaneous test and Calmette's ophthalmic test avoided the severe results of tuberculin, though in the case of the latter the conjunctivitis sometimes set up was the reason for its non-acceptance.

Diagnosis.

When x-ray examination came to be applied to the diagnosis of pulmonary diseases, in practically every case radiating shadows were seen passing from the root of the lung upwards, and frequently patchy shadows in the neighbourhood of the root. Some radiologists looked upon these fan-shaped markings as indicating tuberculous lesions. Dr. Jordan had stated that in every case tuberculous invasion started from the root; in other words, that tuberculosis of the apex was not primary but secondary to invasion from the root along the

lymphatics. X-ray examination was a very valuable help in the diagnosis of pulmonary diseases, but it could not reveal the earliest stage in the formation of tubercle, and it was doubtful whether it could differentiate between active and quiescent lesions. While acknowledging the assistance of the x rays, the lecturer felt that in diagnosis and prognosis reliance must still be placed upon the well-tried methods of physical examination combined with a consideration of the patient's history and symptoms. It appeared to him that at the present day less attention than formerly was being paid to the niceties of physical examination; the younger generation hid off to the laboratories for special examinations before the information possibly to be yielded by ordinary methods had been exhausted.

Treatment.

In reviewing the advances made in the treatment of pulmonary tuberculosis during the last forty years three methods stood out: (1) tuberculin; (2) sanatorium treatment; (3) induction of pneumothorax. It was not surprising that the method of injecting tuberculin, ushered in under such credentials, excited the liveliest interest and hope. In the early days the treatment was surrounded by an atmosphere of mystery. The exact nature of the remedy was not revealed. Doctors in all countries were naturally anxious to make a test, but at first only a limited supply of the agent was available for foreign use. Local results were strikingly manifested in lupus, but when, in accordance with Koch's instructions, the dose of tuberculin was gradually increased, constitutional symptoms of a severe nature were frequently excited, with fatal results in some cases. After a time some workers began to use tuberculin on a different principle, giving increasing doses spread over a considerable length of time so as to avoid constitutional reactions. The results of tuberculin treatment in pulmonary tuberculosis had, generally speaking, been disappointing; better results had attended its use in tuberculosis of the bones and joints. Sanatorium treatment, like treatment with tuberculin, raised extravagant hopes which made disappointment inevitable. Some modifications of the original sanatorium routine had been found necessary. The excessive feeding first insisted on had been abandoned. If permanent benefits were to be secured by sanatorium treatment after-care was necessary, especially in the case of the poorer patients. The difficulty of applying such treatment to early cases was obvious. The diagnosis of the disease in its earliest stage was, generally speaking, at present beyond the powers of medical men. Very few people who had slight symptoms thought it necessary to submit themselves to examination. Consequently patients labelled early by their medical advisers were not really early cases at all. The lecturer's conviction was that this method had given better results than any other so far. Among well-to-do patients there had been cases in which a successful result had persisted for some years. In less successful cases life had been prolonged for a period. One of the great merits of sanatorium life was its educative value for the patient and, through him, for his family. The complexion of the average case of consumption seemed to the lecturer to have altered during the last forty years; in his experience rapidly progressive cases were less frequent, both in private practice and at the chest hospital. For the third of the modern treatments—induction of pneumothorax—the selection of suitable cases was not an easy matter. It was limited originally to cases in which the disease was confined or nearly confined to one side. The tendency during the last few years had been towards a less rigid limitation of the cases submitted to operation. In many apparently hopeless cases great improvement had been gained, and some patients had been able to return to their work. There were obstacles in the way of the adoption of the method in many cases, but as a palliative measure it had its place. He summarized the highly favourable conclusions as to pneumothorax operations given in the recent report of the Medical Research Council (BRITISH MEDICAL JOURNAL, September 30th, 1922, p. 608). On the other hand, in cases of low resisting power and progressive disease, little benefit could be expected.

In conclusion, Dr. Kidd said that great progress had been made during the last forty years in etiology and diagnosis, and, seeing that tuberculosis mortality had fallen considerably, it might be inferred that there had been a corresponding improvement in treatment; but the mortality had begun to fall before the general recognition of the infective nature of tuberculosis, and he attributed the lessened mortality largely to the improved standard of living and more widespread knowledge of hygiene. Segregation of advanced cases was desirable, but it involved the provision of special hospital accommodation on a large scale. It seemed unlikely that the tubercle bacillus could be eradicated. Must they then

despair, and say with Falstaff: "I can get no remedy against this consumption"? If it were true that a large proportion of the population had become partially immune, it might be hoped that future research would discover means of increasing such immunity. The key to the prevention of tuberculosis was the discovery of the biochemical conditions which favoured immunity. If tuberculosis could never be completely exterminated, it would be possible, nevertheless, in the future to bring it under better control.

VIENNA.

SOME RECENT MEDICAL WORK.

Dr. E. W. SCRIPTURE, physician to the Speck Clinic, West End Hospital for Nervous Diseases, London, in a recent address on "Some medical novelties in Vienna," delivered before the Medical Section of the British Psychological Society, touched upon several matters which are now attracting interest in that famous medical centre. In the course of his remarks Dr. Scripture mentioned the magnificently equipped neurological institute now under the charge of Professor Marburg; he described this as a factory for producing research, and observed that one of its workers, Dr. Pollak, has just published an extensive monograph on a piece of British intellectual property that has been annexed by Vienna—namely, "die Wilson'sche Krankheit," the disease named after Dr. S. A. Kinnier Wilson, who first described it. Dr. Scripture next gave a short account of the treatment of general paralysis by malaria inoculation, first proposed in 1887 at the Vienna Psychiatric Clinic by Professor Wagner-Jauregg, and now reinforced by injections of salvarsan. He then referred to the large phonetic laboratory, directed by Dr. Stern at the Throat Clinic of Professor Hajek, where cases of aphonia and defective mutilation are treated by methods of suggestion and re-education. A specialty of this laboratory is the treatment of post-operative cases of carcinoma of the larynx. After removal of the larynx the patient is taught to swallow air into the stomach and then use it to produce sounds. A kind of tone is produced by some constriction in the lower pharynx. This method is very favourably reported on by Dr. Stern. The Vienna Physiological Institute also maintains a laboratory of experimental phonetics, and there is a flourishing society of experimental phonetics predominantly medical in its membership.

Steinach's Operation.

Dr. Scripture then discussed in somewhat greater detail the experimental work carried on by Professor Steinach in one of the departments of the Institute for Biological Research. He said:

As far back as 1912 Professor Steinach published the results of experiments on guinea-pigs and rats in regard to the determination of the sexual instinct and the secondary sexual characters as the results of the internal secretions of the sexual organs. He showed that the transplantation of an ovary in a castrated male causes that male to develop bodily and mentally like a female. Later he showed that when the ovary becomes firmly fixed the feminization goes abnormally far. The male does not stop at taking on the small size of the female with corresponding distribution of hair, development of the breasts, and mentality; the breasts even begin to secrete—without any pregnancy—and the feminized male actually suckles the young that are presented to it. When a testicle is implanted in a castrated female, the genital organs change toward the male type, the bones and muscles become larger, the hair becomes coarse, the general appearance is robust and masculine, manly courage appears, and the animal drives away normal females but attempts sexual activity with a female in rut.

The opportunity arose for an experiment on human beings.

A soldier, 30 years old, had tuberculosis of the testicles—that is, he was practical. The appearance was feminine, his breasts were well developed, and the hair on the body had the texture of a woman's. For many years he had been an actual strong homosexual, taking the passive part. The removal of the tuberculous testicles was indicated. In the same hospital was a man with a painful undescended testicle. The diseased organs were placed in neighbouring beds. The healthy testicle was taken from the soldier and placed in the groin of the soldier. The soldier afterwards took on a manly appearance, became heterosexual in his mental attitude, and subsequently married.

It is impossible even to sketch Professor Steinach's further experiments; only some of the firmly established conclusions

can be summarized. In the first place, the secondary sexual characteristics and mental attitude of the male depend on the internal secretion of the testicles furnished by the interstitial cells, not the sperm cells. These cells are termed the "gland of puberty." Steinach has shown that ligation of the vas deferens, whereby the outflow of sperm is hindered, causes a degeneration of the sperm cells and an increased growth of the interstitial cells. There is consequently an increased amount of the hormone from the interstitial cells passing into the blood. Most remarkable of all is the effect of this hormone on the bodily and mental constitution.

I will now describe a series of photographs shown me by Professor Steinach from a recent investigation.

The first was an anatomical preparation showing the undeveloped sex organs of a normal young rat. The second was a similar one of a fully developed rat. The third was that of a rat whose testicles had been removed in early life and transplanted in the abdominal wall. This rat had grown to full size and was potent. An examination of the implanted testes showed that they contained only interstitial cells and no sperm cells. The fourth was that of a rat of the same age as the last in whom the testicles had simply been removed in early life and not transplanted; this rat had rapidly become old. The fifth was that of a normal old rat with atrophied sexual organs. The sixth was that of an old rat in whom the ductus deferens had been tied in old age; this rat had at once become energetic and sexually potent. The seventh was that of a rat killed at the age of 1 year; at birth he had been removed and kept absolutely alone; his sexual organs had not developed to the normal size but had remained infantile. The eighth was that of a rat of the same litter likewise kept isolated for a year but thereafter placed with females. He became strong and potent. After he was killed his sexual organs were found to be of normal size, but the testicles contained almost entirely interstitial cells and very few sperm cells.

Professor Steinach has a theory that there are two kinds of interstitial cells, the small and the large. Each produces a hormone that controls the sexual instincts. One set gives the driving force to the heterosexual impulse, the other to the homosexual impulse. According as one kind or the other predominates, the animal becomes heterosexual or homosexual. This theory would come as a shock if we had not already been prepared for it by psycho-analysis. We now know that all human beings possess both these impulses at and after birth; whether the child later becomes predominantly heterosexual or predominantly homosexual depends, according to the analysts, on the way in which he is brought up. The average boy becomes predominantly heterosexual because he is first attached to his mother and is later able to transfer his attachment to other females. He may become homosexual because the homosexual attachment may be made predominately by over-attachment to father or brother, or because an intolerable over-attachment to mother may be so violently suppressed that it drags with it all the heterosexuality, leaving the homosexual element alone active. A similar result may occur where heterosexual attachment is difficult or impossible. According to Steinach, however, the final predominance is determined simply by the relative degrees of development of the two kinds of cells.

These two views need not be conflicting. Professor Steinach says—and I am certain he does not mean to joke—that psycho-analysis (as well as all psychic treatment) has an effect because it alters the internal secretions and thereby influences the bodily and mental character. This means that the mental influences of childhood go along with changes in the endocrine glands.

There is a type of patient that is the despair of the general practitioner and the physician in the out-patient department.

As an example I will take the case of a stone-polisher, 47 years old, who complains of "I do any work. He falls asleep during the day on a chair. His memory has become very poor. In two years he has lost 50 lb. in weight. He is quite unable to earn his living. He looks emaciated, aged, and depressed. The hair on his temple is grey. Hands and ears are evanescence and cold. Bodily investigation shows nothing abnormal. The Wassermann reaction is negative. The general practitioner would probably make a diagnosis of early arterio-sclerosis, and would continue to give potassium iodide and certificates of "unfit for work" until the end of his life.

A psycho-analyst would recognize this as a very common type of mental disturbance that might be curable by proper analysis. Such a diagnosis, however, does not help the patient in the least. He is a poor man, and psycho-analysis is only for those who can pay good fees. Apparently the case is hopeless.

I have purposely chosen this case from the advance sheets of a book that will shortly appear by Dr. Schmidt of Berlin giving his results with the Steinach operation.

On February 7th this patient underwent the operation of vasoligature on the right side. On March 10th he states: "To-day I can count the tiles on the roof opposite, which five weeks ago

appeared to me only as a confused mass. I am as well now as I ever was. My mind is clear. The tiredness has gone. I can work as well as formerly." On April 15th he was seen again. He looked fresh and rosy and much younger than 47. He was working daily from 4 in the morning till 6 in the evening. On October 10th he was seen once again. He looked like a man in the thirties. His hair had become dark brown and much thicker. He had undertaken a very large piece of work and carried it out with an intensity and joy such as he had never before had in his life.

Dr. Schmidt reports a whole series of such cases, with similar results. There are also other cases in which no benefit is obtained. In going over his histories I am struck with the fact that he does not seem to have made a previous psychological study of them. The proportion of successes would have been still greater if certain types had been excluded.

With the Steinach operation the ligation of the vas deferens hinders the outflow of sperm. This at once produces pressure on the interstitial cells and accelerates their internal secretion into the blood. This causes the sudden rejuvenation of the first few days. Thereafter there is a pause. The sperm cells degenerate and are replaced by increased numbers of interstitial cells. This is followed by an abnormal amount of internal secretion. This, as was first shown in the case of rat No. 8 above, produces a real rejuvenation of the tissues. The patient actually becomes a younger man.

Steinach has given no explanation of the effect on the mind in such cases. I may suggest that the internal conflicts due to repressed unconscious complexes have been kept down as long as the person was young and vigorous. With exhaustion or shock or approaching age the diminished vitality lessens the control of the conscious mind and the complexes have a chance of breaking forth and more or less disabling the person. The rejuvenation, I suggest, brings back the energy needed for the repression.

The problem lies before us of introducing the Steinach operation into general and hospital practice for suitable cases. It is not expensive. If the cases are suitably selected it is highly successful. It does not interfere with the procreative power because it is done on only one side. A successful result restores the man to work, whereby he becomes a useful member of the community instead of a living corpse. It usually restores his potency.

The relation of the Steinach operation and other forms of hormone therapy to psycho-analysis is a very close one. Even if we do not believe that psycho-analysis acts only by changing the action of the endocrine glands, and that the changes in character result from the glandular changes, and not directly from the analytical treatment, yet we can think of the possibility—at least in some cases—of using hormone therapy instead of psycho-analysis. The possibility of curing a portion of the countless cases of anxiety neurosis (including hysteria) by a simple inexpensive surgical operation is worth considering. The problem is also important to the analytical specialist. With quite a large number of patients undergoing psycho-analysis the point is reached where the resistance proves too great to be overcome. The treatment must then be broken off as hopeless. The patient thereafter usually falls into a condition of secondary repression which is worse than the original one. Such a result is more common in advanced life. It is in just such cases that perhaps a Steinach operation would effect a cure.

Dr. Scripture next recounted a case bearing upon the interpretation of patients' dreams, with the object of bringing out his contention that the main psychological complex may be quite other than the sexual complexes usually sought for by psycho-analysts. He concluded his address with a brief tribute to the efforts of the Vienna Medical School to rise above the misfortunes of the present time.

To those of us who know and love Austria (he said) there is something deeply touching and profoundly inspiring in finding that in Vienna the devotion to scientific research still remains a vital force amid poverty and disaster at a time when most of the rest of Europe is mainly concerned in using the situation for commercial profit. The nation that can still maintain the University of Vienna deserves a better fate than to become the exploited slave of international financiers.

THE next French Congress of Medicine will be held at Bordeaux in 1923 under the presidency of Professor Arnozan, when the following subjects will be discussed: remote sequelae of malaria, relations between the sympathetic and endocrine glands, and treatment of meningococcal infections.

OWING to a scarcity of rabbits the Breslau Pasteur Institute has decided that everyone applying for antirabic treatment must supply at least two rabbits, the price of which will be refunded by the Institute.

British Medical Journal.

SATURDAY, NOVEMBER 18TH, 1922.

ANIMAL AND PLANT PATHOLOGY.

WE turn from the study of human disease to consider the morbid processes affecting animals and plants in the hope that here may be found an answer to some of the problems which laborious research on human infections has hitherto failed to solve. Diseases in plants and animals can be investigated by the experimental method, the origin, course, and treatment of disease being examined with a thoroughness rarely possible in human patients. Comparative pathology is studied also for reasons of public health. The animals with which we are often in contact are themselves liable to invasion by bacterial enemies, many of which are capable of infecting man, and the diseases by which plants are beset, though not directly transmissible to man, are of great economic importance. In moments of reflection also our thoughts may turn from the more pressing claims of human disease to notice how in every manifestation of life health is constantly in jeopardy. Fevers and distempers disturb the existence of birds; mammals and reptiles, fishes, insects, and worms are liable to invasion by unwelcome parasites; trees suffer from tumours, cereals from blight; and even tobacco does not escape from the ultramicroscopic filter-passing virus. Throughout the animate world perfect health is a very rare gift.

But, it may be asked, can we hope to derive any practical benefit to human medicine by a study of the diseases of animals and plants? The knowledge of the rudiments of botany and zoology which the medical curriculum prescribes ensures a broad-minded outlook on the natural world; this having been assured, at least in theory, what expectation have we that an excursion into the realms of plant and animal pathology will yield information of value in the study of human disease?

The problem is not a new one for the British Medical Association. The possibility of getting light from vegetable pathology was brought to notice over forty years ago by Sir James Paget in an address to the Section of Pathology at the Annual Meeting at Cambridge in 1880. Sir Clifford Allbutt, in his Address in Medicine to the Annual Meeting in Glasgow in 1888, covered a rather wider field, and in his presidential address in 1920 to the Annual Meeting of the Association in Cambridge he returned to the subject. In the Section of Pathology (Human and Comparative) at Glasgow this year a discussion on animal and vegetable pathology in relation to human disease was opened by Professor Frederick Hobday, F.R.C.V.S. During that discussion, a report of which is published in our issue this week, Professor W. H. Lang warned students of comparative pathology against the snare of false analogies, but Sir Clifford Allbutt, who followed, desired to delete the word "false," maintaining that argument by analogies had been the bane of medicine from the earliest times. The path of advance, he said, was to go beneath analogies and similitudes to underlying affinities, which, indeed, were often far from apparent.

It must be admitted that only with the greatest caution can comparisons be made between diseases of plants and the diseases of animals, since the structure of the tissues is so fundamentally different, the characters

of the infecting agents so diverse, and the mechanism of resistance based on such opposite systems. Animals provided with a general circulation of body fluids can bring to bear on an infective agent protective substances derived from all parts of the organism in the attempt to save the health of an injured member; plants, on the other hand, can only resist locally, and often the wisest plan is to isolate the infected area and sacrifice the diseased tissue. Yet in spite of these apparent dissimilarities, in all manifestations of life the nature of this reaction is fundamentally the same—namely, an attempt to preserve the integrity of the cell against an injurious agent. The protection of the cell is the basis of immunity in plants, in animals, and in man, yet we know almost nothing of the means by which it is secured or the defects which lead to its default. Researches in resistance to human disease have been concerned chiefly with acquired immunity, and we are now fairly well informed of the reactions which take place in an infected area and of the protective substances which make their appearance in the body fluids. But of natural immunity and the security enjoyed by individual cells we know no more than is expressed by the word "susceptibility." The difficulties which beset the study of natural immunity in man are great, but it is probable that light will be thrown on the problem by the study of the phenomenon as it presents itself in plants and the lowlier forms of animal life; the prospect of enlightenment in this way warrants the closest interest in comparative pathology.

Professor Hobday's review of the diseases communicable from animals to man proves how important comparative pathology is from the point of view of public health, and indicates the extensive benefits the community has derived from advances already made. Thanks to the efficiency of the veterinary service, glanders and rabies are practically stamped out in this country, whereas only twenty years ago glanders in horses was common, and many human beings were exposed to this terrible infection. If, however, there is reason for congratulation on what has already been accomplished in certain fields, there is reason for shame also at the paralysis which has overtaken administrative measures designed to combat the most widespread of all communicable diseases—namely, tuberculosis. There are at present a million tuberculous cattle in Great Britain, and it is reckoned that over 10,000 children die annually from drinking tuberculous milk, yet the Cattle Tuberculosis Order, which was temporarily suspended during the war, has not been re-established. Professor Hobday states on behalf of the veterinary profession that, given a free hand, they could stamp out tuberculosis in cattle in the same way as they have already stamped out glanders and rabies; and he calls on the medical profession to assist in bringing pressure to bear upon the authorities for the re-institution of the Cattle Tuberculosis Order.

Disease processes in plants are worthy of study not because of possible transmission to man, but because they may yield a clue to some of the mysteries which enshroud malignant disease in man. Professor Lang described that remarkable disease crown gall, but although he warns us against drawing inferences from morbid processes developing in such fundamentally different tissues as those of plants and animals, yet the resemblances are very striking and provide material for thought. The tumour-like growths of crown gall follow the inoculation of the tissues of the plant with *Bacterium tumefaciens*, and consist of irregular masses of cells stimulated to riotous overgrowth by the presence of the infective agent. The first response of the plant to this infection is merely an exaggeration of the normal process of wound irritation, but the same comment is equally

applicable to human neoplasms, since in these also irritation is often an important factor in the early stages. Later the cells of the crown gall tumour invade the normal tissues and set up secondary tumours at a distance, a sequence of events reminding us at every point of the familiar features of malignant disease. If we know as much of the initiation and spread of cancer as we do of the tumours of crown gall a notable advance would have been achieved.

The nature of the so-called filter-passing virus is a fascinating problem. Here the investigator is dealing with a form of life too small to be seen with the highest magnifications of the microscope, and yet capable of initiating grave disturbances in both animals and plants. The first demonstration that disease can be caused by a filtrable virus was made in the plant disease known as tobacco mosaic, and many other plant diseases have since been shown to be due to ultramicroscopic organisms; the number of human diseases attributable to this form of infection is yearly increasing. The plant pathologists have taught us much concerning these infections. They have proved that these virus diseases are commonly transmitted by the bites of insects; they have established that these diseases can be hereditary both in host-plant and in insect; they bring forward evidence against the probability of any saprophytic life for these organisms, and have indicated how very dependent this form of life is on suitable environmental conditions.

Hitherto the diseases of man, animals, and plants have been studied by three separate specialized groups of workers—the human, the veterinary, and the plant pathologists; each has proceeded along separate lines of inquiry, and there has often been lamentable ignorance of the progress made in the kindred sciences. Yet many diseases are common to man and animals, and in the study of them—we may instance anthrax—it is obviously desirable that veterinary and medical pathologists should combine. In fact, the number of diseases of plants or animals which either directly or indirectly affect the health of man makes a long list; of the essential details of the disease processes in animals and plants the medical pathologist should be accurately informed. But the subject will be of interest not only to pathologists, and not only on account of the questions of public health which we have seen to be so intimately involved. Echoing the words of Sir Clifford Allbutt, we will venture to assert that the significance of disease will never be rightly understood if attention is confined to those morbid processes affecting man which it is our duty as a profession to attempt to relieve. Ill health is often attributed to constitutional defects and perverse habits; in a limited sense this may be true, but we are all familiar with diseases which attack the strong and spare the weak. May we not recall the rebuke: "Those eighteen, upon whom the tower in Siloam fell, and slew them, think ye that they were sinners above all men that dwelt in Jerusalem?" Bacteria were not created for the express purpose of inconveniencing or punishing man; they came into existence to perform an indispensable function in nature, and life on this planet is only possible thanks to their ceaseless activities. Throughout the animal and vegetable kingdoms we find the incessant conflict of two forces, one endeavouring to preserve health, the other attempting to undermine it. In many plants the dispute is settled by the establishment of symbiosis, in which both forces combine to work for the common good. It is possible that even in man this happy compromise is sometimes achieved. By reflecting on this conflict as it manifests itself throughout the natural world we shall escape from too narrow an outlook on the question of health and disease.

THE TREATMENT OF DIABETES BY INSULIN.

RECENT scientific work in the laboratories of the University of Toronto, the nature of which was described in some detail on November 4th (p. 833) by Dr. J. J. F. Macleod, Professor of Physiology in that University has yielded results which, it is perhaps not too sanguine to hope, have opened a new chapter in the history of the treatment of diabetes. As our readers have learnt from Professor Macleod, the effects observed in animals have justified the trial of insulin in man, and diabetic patients have eagerly flocked to take advantage of the new treatment. It consists in the administration of a substance, to which the term "insulin" has been applied present in an extract made by a new method from the pancreas of the ox, pig, or sheep. The authorities of the University have taken special measures, appropriate to an exceptional situation, to protect and control the manufacture and use of this substance in Canada and the United States, and they have offered as a free gift to the Medical Research Council all rights in a patent covering the product and the process of its preparation for which application has been filed in this country on behalf of the University of Toronto. The University has done this with the object of putting into the Council's hands the means of exercising the same powers of control over the preparation of this important new substance for trial in this country as the University has found it desirable in the public interest to exercise in the American continent. Representatives of the Council have recently visited, by the courtesy of the University the various centres of work in Canada and the United States, and have examined closely the progress already made there, with a view to finding the conditions under which the production of insulin for a careful trial of its properties may best be accelerated in this country. In view of the great importance and growing interest of this subject, both to the public and to the medical profession, the Medical Research Council, which has accepted the generous offer of the University of Toronto has now made a public statement of the present situation and of the considerations by which the policy of the Council is being guided.

At the outset it is explained that the new substance insulin is not yet available in this country in any form. It is being made on a moderate scale at Toronto, and on a small experimental scale in one or two laboratories in the United States, and these sources of supply are hardly sufficient for the daily needs of the diabetic patients selected for experimental treatment at those places. Under control and guidance from Toronto, manufacture by one American firm is being developed upon a large scale, but no supply at all is yet available for the medical profession in general. The preparation and administration of insulin are alike still in the experimental stage.

There can be little doubt, as we observed a fortnight ago, that the new treatment opens a bright prospect of relief, of longer life and less severe deprivation, to many of the sufferers from a disease so distressing and hitherto intractable as diabetes. The improvement of the methods of the preparation and administration of insulin, and the determination of the limits of its efficacy—whether in any cases and by any method of application it can effect a permanent cure, or only, as hitherto, relieve at each administration an incurable defect—these are matters urgently demanding further research.

The active pancreatic principle (insulin) is of unknown chemical nature, and is easily destroyed in the course of its extraction. The possibilities of the new treatment

have sprung from the discovery of a method whereby this active substance can be extracted and freed from concomitants which, when ordinary methods are used, lead to its rapid destruction. A process which succeeds on an experimental scale in the laboratory presents now and much more serious difficulties on a large scale in the factory. Even under the best conditions yet available it appears that great variations in activity may occur between individual batches of the extract, made without any known variation of the process. While the use of an inactive preparation would bring painful disappointment to the patient and bring the treatment into undeserved discredit, the use of a preparation of unexpectedly high potency may be definitely dangerous. No indication of the activity, and so of the remedial value, can be obtained except by experiments on the potency of each sample, previous to its actual use for a patient in the hospital ward, and these require a well-equipped physiological and biochemical laboratory. The degree of permanence and condition of stability of the extract are as yet practically unknown. In face of these conditions, to leave the production of the remedial extract to unassisted and uncontrolled commercial enterprise would be to imperil the credit and success of the treatment, and entail for many sufferers not only disappointment but serious danger. Apart from any of the obvious possibilities of improper exploitation, it is clear that even preparations made with a conscientious effort to adhere to the methods and precautions so far indicated by the discoverers might prove to be at once useless and harmful.

In these circumstances the Medical Research Council has considered it a duty to use any means placed at its disposal for safeguarding, while accelerating, the proper production of this remedy. The Council is already arranging for the preparation of insulin for trial and study at several hospital centres where the necessary facilities exist. The scientific workers who accept this responsibility will undertake to work as members of a co-ordinated team in close touch with the National Institute for Medical Research at Hampstead, with a view to achieving the most rapid progress possible towards improved methods of preparing and of using the extract. At the same time, and independently of this immediate research work, the Council is considering under what conditions it may be possible to grant licences to private institutions or factories having proper facilities for making and testing the extract. It may be that some of the existing commercial organizations may find it possible to deal satisfactorily with the problem of providing insulin and of keeping pace with the demand. This demand will grow rapidly and continuously if the methods of treatment and precautions against danger become so simplified by research work that the remedy can pass into general, as distinguished from hospital or specialist, practice. It may prove, on the other hand, that the needs of the situation can best be met by a special organization, established with the primary aim of relieving the many sufferers from diabetes, and with no view to making profits on an ordinary commercial basis. If this should prove to be the most effective method for providing the remedy, money for its establishment would be needed. The Medical Research Council has no funds at present which it could apply to such a purpose.

The intention of the Council is to promote, in the light of recent experience in Canada and of such new knowledge as research will gain, whatever enterprise or organization is best fitted for securing the earliest production of the insulin extract under proper conditions of safety and control, and so to facilitate, with the least possible delay, a thorough and scientific trial of the new

THE AUSTRALASIAN MEDICAL CONGRESS, 1923.

On November 4th we published, at page 890, a short note from our Victorian correspondent on the sectional arrangements for the Australasian Medical Congress to be held in Melbourne in November, 1923. At the last meeting of the Central Council (as recorded in the SUPPLEMENT of November 11th, p. 175) a communication was read from the President of the Congress (Mr. G. A. Syme, M.S., F.R.C.S.) calling attention to this event and to the fact that it would be the first session of the Congress to be held under the control of the Australian Branches of the British Medical Association and of the Branches in New Zealand. Mr. Syme's letter conveyed a request that the President of the Association, or some distinguished officer, should attend the Congress. This invitation was most cordially received and the Finance Committee was instructed to consider ways and means. The President, Sir William Macewen, said that he had all the will to go, but would like a little time to think over the project before making a decision; we know we express the view of every member, both here and overseas, in hoping that he may find it possible to accept. We have now received from Dr. A. L. Kenny, the General Secretary, an advance proof of the preliminary programme for the Congress. He tells us that the aim of the local executive is to make this meeting in Melbourne a memorable occasion in order to ensure a long sequence of successful congresses under the same control. "We hope," he adds, "to be in the position to give a very cordial welcome to members of the parent Association, and to this end we invite your powerful aid." The Congress will be held in the buildings of the University of Melbourne from November 12th to 17th. The Patrons are the Governors-General of the Commonwealth of Australia and the Dominion of New Zealand, and the Governors of New South Wales, Victoria, Queensland, and Western Australia, and the Chancellor of the University of Melbourne. The Vice-Presidents are distinguished representatives of the science and practice of medicine in the Commonwealth, the Dominion, and in Tasmania. The treasurer is Dr. C. H. Mollison, and Dr. Kenny is assisted in his secretarial duties by Dr. F. L. Davies and Dr. W. S. Newton. Besides these honorary officers in Melbourne there are local secretaries in Sydney, Brisbane, Adelaide, Perth, Auckland, Dunedin, and Hobart. The scientific work of the meeting has been organized in the following sections: Medicine, Surgery, Obstetrics and Gynaecology, Pathology and Bacteriology, Preventive Medicine and Tropical Hygiene, Ophthalmology, Otolaryngology and Rhinology, Neurology and Psychiatry, Diseases of Children, Naval and Military Medicine and Surgery, Dermatology, Radiology and Medical Electricity. Officers have been appointed for each section, and the general arrangements for the Congress are in the hands of a number of committees; the plan thus follows very closely that of the Annual Meetings of the parent Association. We note with interest that much prominence is given to a resolution of the Executive Committee as follows: "In all the work of the Congress particular attention shall be given to the preventive aspect, including medical research." Another matter of a different kind, though well worthy of note, is that the Railway Commissioners of the Commonwealth and of the Australian States have agreed to make generous reductions in the price of railway tickets for those attending the Congress. In this respect the Australian railway authorities have shown good sense and public spirit. It is to be hoped that the British Railway Clearing House, which declined to grant reduced fares for the Annual Meeting at Glasgow, will follow the example from overseas before the Association meets in Portsmouth next summer. All communications regarding the Australasian Medical Congress should be addressed to Dr. A. L. Kenny, Medical Society Hall, Brunswick Street South, East Melbourne, Victoria. We wish him and his colleagues every success, both in the quality of the work done and in the number of those who attend.

INTRATHORACIC SURGERY.

When Sir William Macowen first showed that the thorax could be opened without collapse of the lungs the importance of his observations and operations does not seem to have been sufficiently appreciated by surgeons; at any rate, his methods were not adopted in general surgery. This failure to appreciate a new observation is not uncommon, and is difficult to explain. The fact remains that Macowen's work remained almost unrecognized until the progress made in intrathoracic surgery during the war won acknowledgement for it. Of how great that progress has been Mr. T. P. Dunhill, assistant director of the surgical unit at St. Bartholomew's Hospital, has given some striking instances in a paper published recently in the *British Journal of Surgery*.¹ "Fear of the unknown within the thorax has," he says, "hitherto made us pause in dealing with tumours in this part of the body. . . . A greater familiarity is tending to remove our fear." The article describes three intrathoracic tumours removed through an incision which split the upper half of the sternum, a method of approach which Professor Gask had practised even before the war. In the first case a fibroma growing from the spinal column occupied the dome of the right thoracic cavity. Intratracheal anaesthesia was employed, in order, as Mr. Dunhill states, to prevent collapse of the lung when the thorax was opened. The tumour seems to have been fairly easily freed from its surroundings save for an attachment to the pericardium covering the body of a vertebra. This attachment was divided without difficulty or troublesome haemorrhage. The result was complete recovery after an uneventful convalescence. The second case was one of an elongated colloid adenoma of the thyroid, the upper end of which was visible in the neck, while the lower portion extended down behind the sternum to the level of the seventh dorsal vertebra. The tumour was attached by dense adhesions to the aortic arch and other neighbouring structures. The sternum was divided longitudinally and then transversely at the level of the third costal cartilage, so that the anterior thoracic wall could be opened by double doors as it were. The tumour was separated and removed intact. It is interesting to note that in this case intratracheal anaesthesia was not used, but the operation was performed under open ether without apparent disadvantage. Evidently collapse of the lung (to avert which intratracheal anaesthesia had been chosen for the first case) did not occur in this patient. The after-result suggests that the tumour, although removable, was malignant, and it is feared that recurrence of the growth has begun in its original site. The third case was one of retrosternal cystic adenoma of the thyroid. Local anaesthesia was employed and the tumour removed after splitting the sternum. Adhesions to the aorta had to be separated; the manipulations must necessarily have been very gentle, and do not appear to have offered grave difficulty or danger in either this or the former case. The patient made a good recovery and remains greatly relieved. The record of these operations shows how far we have advanced with intrathoracic surgery. It might of course be argued that cases requiring such operations are so rare in civil practice that these surgical procedures can only be embarked upon with any prospect of success by surgeons who became familiarized with intrathoracic methods by vast and rapidly gained experience in battle surgery. The history of abdominal surgery does not bear out this view. Once the way has been proved practicable the careful surgeon of the future should not find it difficult to follow. Intrathoracic surgery has been established, and we feel confident that we are on the eve of a new era. One point in particular requires emphasizing: these operations can be safely performed under any form of anaesthesia. Macowen had proved that elaborate pressure chambers were unnecessary for the performance of thoracotomy. Gask and Dunhill have confirmed this and shown in addition that neither local nor intratracheal anaesthesia is essential. It is not every patient who is

suitable for operation under local anaesthesia, nor, if we may say so, is every surgeon fitted temperamentally for operating with his patient conscious and anaesthetized only in the area of the operation. One further remark may be ventured. During the pioneer stages of intrathoracic surgery the public will, perhaps, consider that such operations are more safely performed by the surgeons who have made them their particular study. Yet by the terms of appointments to the surgical unit at St. Bartholomew's private patients cannot, so we understand, have direct access to the knowledge and experience of Mr. Dunhill or Professor Gask if they should stand in need of such operations as form the subject of this paper.

SMALL-POX AND VACCINATION.

In the pamphlet on small-pox and vaccination the Research Defence Society has very opportunely issued it is pointed out that there are in England and Wales at the present time about fifteen million persons unprotected against small-pox, and that among them are multitudes of unvaccinated children. Reference is made to the epidemic in Gloucester in 1895-96, when 279 unvaccinated children under 10 years of age died of small-pox, while only one child died out of more than 8,000 who were vaccinated before or during the epidemic. Another instance of how small-pox picks out the unvaccinated children was the outbreak which occurred in 1903 at Ossett, in Yorkshire, where, in a school of 169 children living under similar conditions, of the 14 vaccinated pupils none took small-pox, of 78 vaccinated pupils 5 took small-pox, and of 77 unvaccinated pupils 37 took small-pox. A very usual argument of antivaccinationists is that small-pox has been abated, not by vaccination, but by sanitation. It is controverted by many historical facts. For example, the immediate results of Jenner's discovery of vaccination in 1796 were not due to sanitation. The great abatement of small-pox was already achieved by 1812, while the rise of modern sanitary science came later, with the work of Edmund Parkes, Sir Edwin Chadwick, and Sir John Simon; the Public Health Act did not become law until 1875. The pertinent question is put—Why, if sanitation alone were sufficient to prevent epidemic diseases, have not measles, diphtheria, scarlet fever, and whooping-cough been reduced to the same extent as small-pox? No one contends that vaccination is our one and only defence against the spread of small-pox—the disease is fought also by sanitary measures, but sanitation alone is insufficient. Pamphlets for the instruction of the lay public as to the risks of small-pox and the value of vaccination have been published from time to time—by the British Medical Association, for example, and recently by the Ministry of Health.² These have proved useful for their purpose. The present outbreak has furnished opportunity for similar effort, and in addition to the Research Defence Society's pamphlet Dr. McConnell Wanklyn has published in attractive form an address³ to the Society of Medical Officers in March last. The pamphlet differs from other tracts in presenting to the public a pronouncement made by a medical man to medical men, so that there can be no suspicion of special pleading or polemics; at the same time, it is an address which any layman can understand. Also, he has issued through the same publisher a leaflet at the modest price of 2d., addressed to the public. The most directly successful advocate of vaccination, however, is small-pox itself, as is at present being witnessed in London. Up to November 14th cases treated by the Metropolitan Asylums Board since October 25th had increased to fifty, of which fifteen had proved fatal. Forty-five of the fifty were in Poplar. A case has occurred in Shoreditch, another in Lincoln, another in Paddington, and it has been stated that cases have occurred also in Lambeth, Tulse Hill, and Streatham, but we have not been able to verify these. A scheme of "mass vaccination" is being taken up by many leading business firms in London, whilst the Westminster

¹ BRITISH MEDICAL JOURNAL, August 19th, 1922, p. 316.

² A Survey of the Present Position of Small-pox and Vaccination affecting this Country. G. A. Warcham, 90/91, Queen Street, Cheapside, E.C.4. (Pp. 23. 1s.)

Guardians have authorized their public vaccinators to vaccinate persons employed in Westminster though resident elsewhere.

THE STRASBOURG MEDICAL DEPUTATION.

On the evening of Wednesday, November 8th, the Fellowship of Medicine gave a small dinner, hastily arranged, to meet members of the delegation from the University of Strasbourg, who, as we mentioned a fortnight ago, on their return from an inspection of medical schools in America, visited this country with the same object. Sir George Makins, President of the Fellowship, was in the chair, and Sir Humphry Rolleston, President of the Royal College of Physicians and Chairman of the Executive Committee of the Fellowship, was among the hosts. The members of the Strasbourg delegation present were Dr. Maurice Nieloux and Dr. Lucien Pantrier. Dr. Nieloux, who is professor of physiological chemistry in the University of Strasbourg, has done much important work in pharmacology, particularly with reference to alcohol. For a time he was associate professor in the University of Paris, served during the war, and was appointed to the University of Strasbourg at its reorganization in 1920. Dr. Pantrier is professor of dermatology and head of the cutaneous diseases clinic at Strasbourg; he is particularly known for his writings on tuberculosis of the skin. He also served during the war and was appointed to the University of Strasbourg at the time of its reorganization. After the health of the King and that of the President of the French Republic had been duly honoured, Sir George Makins gave a toast to the University of Strasbourg; he recalled its long history and mentioned some of its many vicissitudes, including the period of over forty years during which it was a German university; he also spoke of the fine temper shown by the French in the reorganization of the University, and praised the enterprise of the faculty in sending a delegation to America and Great Britain to study methods of medical teaching and research. Sir StClair Thomson, chairman of the Social Committee of the Fellowship, followed with a spirited speech, in French, during which he expressed the fear that the delegation might not have learnt much in studying the English system of medical education, since there was, in his opinion, no such system, each school having its own individualistic methods. Professor Pantrier, in reply, immediately countered Sir StClair Thomson by asserting that the delegation had indeed learnt much in Great Britain and that the very fact that the schools each had so much individuality was in itself a lesson. He sketched some of the recent developments of the University of Strasbourg and expressed the hope that many members of the British profession would visit the city next year during the celebrations of the hundredth anniversary of Pasteur's birth. Immediately afterwards the company adjourned to the house of the Royal Society of Medicine, where that evening a conversation was held, during which Sir John Bland-Sutton charmed a very large audience with the address "Spolia nemoralia," published in our columns last week; during his address he exhibited the specimens illustrated in our report of his address. They are to be placed in the Museum of the Royal College of Surgeons of England. The dinner was a model in its way; it was timed for seven o'clock, started a few minutes afterwards, and was over by twenty minutes to nine. Judging from remarks we heard, those present, who included many ladies, enjoyed the dinner far more than if it had been prolonged by many set speeches.

HEALTH PROBLEMS IN THE WEST INDIES.

An article in *United Empire*, the journal of the Royal Colonial Institute, for November, 1922, by Dr. G. B. Mason, discusses many points of importance in regard to health problems in the West Indies. The need for improved conditions of public health and sanitation and for an efficient and adequately paid medical service has lately been emphasized in the report on the West Indies by the late Under-Secretary of State for the Colonies, the Hon. E. F. L.

Wood, and by the resolutions passed by the West Indian Medical Conference at Georgetown, British Guiana, in July, 1921.² The latter conference made twenty-three recommendations to the Secretary of State, but Dr. Mason points out that it did not refer to the high infantile mortality and death rate prevailing in the West Indies, which are preventable, to the absence of suitable quarters for married men in many districts where medical officers are required, nor to the provision of an adequate nursing service under Government control. In his paper Dr. Mason gives an analytical table of the different British colonies in the West Indies, their population, revenue, birth rate, death rate, infantile mortality rate, and the percentage of the revenue spent on medical services. In 1920-21 the total trade of Bermuda, the British West Indies, British Guiana, and British Honduras amounted to £85,532,328, and the four colonies of Barbados, Trinidad, Jamaica, and British Guiana each had a total trade of over ten millions. The ratio of total revenue to total trade shows that taxation is light, usually about 10 per cent.; the percentage of revenue spent on medical and allied services varies from 4.44 in Bermuda to 18.82 in Antigua, with an average of about 10 per cent. In the last report of the chief medical officer of the Ministry of Health it is shown that the percentage of the total amount of rates for England and Wales in 1919-20 applied to expenditure on health was 21.9 per cent. The birth rate in the West Indies is much higher than in Great Britain, but the infantile mortality rate is in many cases appalling; it is for instance 270 per 1,000 births in Barbados, 233 in Antigua, and 322 in St. Kitts. In the last named island this may be partly accounted for by the fact that the illegitimate births are more than three times the legitimate births; similarly in Antigua the illegitimate births far exceed the legitimate births, and the children die through poverty, neglect, and ignorance. The infantile mortality of St. Vincent is lower than that of any other of the islands—except the small and prosperous island of Anguilla, with a population of just over 4,000, where special conditions exist—and is lower than that of the other islands in the Windward group; it is suggested that this is due to the fact that trained Government midwives practise there. The facts elicited by Dr. Mason's analysis show an extremely unhealthy condition of affairs in many of the West Indian islands. It has, however, much to say in the way of constructive criticism; he advocates the establishment of a proper system of public health administration in the West Indies, including full-time medical officers of health, sanitary inspectors, district medical officers, and Government district nurses. He suggests that it would be a financial economy to have properly equipped hospitals in the towns, to which all serious cases could be sent by boat or ambulance by the district medical officers. Unless a Government district nurse is within reach, the nursing which a patient could be expected to receive in out-districts in the West Indies is, he states, very primitive, and not of the kind that would help the doctor's treatment. The excuse given, of course, for the prevailing conditions in many of the West Indian islands is their lack of money, but Dr. Mason has performed a valuable public service in showing that even under the present financial conditions of the islands the proportion of the revenue spent upon health is entirely inadequate, and should be increased.

VENEREAL DISEASE AS A WAR CASUALTY.

At the War Section of the Royal Society of Medicine on November 13th Surgeon Rear-Admiral W. Bett, in opening a discussion on "Venereal disease as a war casualty," gave figures showing the incidence of venereal disease in the British army at different periods. In 1860 it was 316 per 1,000 of strength; in 1895, 238; and in 1911, 114. In 1922, during the first half of the year, he believed it had come down to 34. In 1888 the percentage of venereal disease to all diseases was 30.7; in 1912, 16.3; and in 1921, 7.5. In 1888 the number of cases of gonorrhoea and syphilis were approximately the same; in 1921 (in the southern command) there

were 3.3 cases of gonorrhoea to 1 of syphilis. The figures for the navy did not fluctuate as widely as the military figures. In 1870 the admission ratio in the navy was 98 per 1,000; in 1913 it was 93; in 1915, 67. Syphilis was supposed to have been very prevalent in the French army during the eighteenth century, and in the Peninsular wars it was rife. In the Crimean war the British army did not appear to have suffered severely; in most cases the disease was contracted at home. The incidence in the Baltic fleet during that campaign was 47 per 1,000, and in the Black Sea fleet, which was farther from home waters, 26 per 1,000. In the South African war the incidence in the British army was diminished, though there was an increase after the war. It was difficult to get precise figures for the European war. In 1917 from 7,500 to 9,000 cases were constantly in hospital in the United Kingdom. In France during the same year it was calculated that there were about 8,000 cases constantly in British hospitals. In both services much had been done to combat the disease. Lectures were given in all ratings, and measures of personal prophylaxis described in detail. Men were made acquainted with the earliest symptoms in order that they might report at once, and concealment had become quite uncommon. His own opinion was that the evil was so great and widespread, and so apt to involve the innocent, that almost any measures were justifiable if only they were efficient. The best method of prophylaxis seemed to be thorough washing with soap and water immediately after the act, together with micturition. Ointments and lotions should also be used if available. It seemed quite clear that "packets" had been of great service in causing diminution of the disease. Much could be done also by the encouragement of games, the provision of reading rooms, and instruction in handicrafts and the like. Colonel P. H. Henderson said that in the command in which he was serving the incidence of gonorrhoea had been reduced very little since the introduction of prophylaxis. In 1913 the ratio was about 24 per 1,000, and in 1921 it was 21. The incidence of syphilis, on the other hand, was 16 per 1,000 in 1913, and 6.12 in 1921. He did not put the whole of this improvement down to prophylactic measures; officers of units were now taking much more interest in sports for their men and in the comfort of barrack life. Sir Robert Hill, Medical Director-General, R.N., said that the incidence of venereal disease in war depended largely on opportunity. In the big ships of the Grand Fleet, on which shore leave was given only once a year, the incidence was lower in war than in peace; whereas in the destroyers, which could not go on for longer than three months without refitting, the conditions as to venereal disease became alarming—at one period one-third of a ship's company was infected. Major A. T. Frost thought that prophylactic outfits had failed, not so much because they might not prevent the disease, as because they were difficult for the average man to use. Sir William Macpherson agreed with Rear-Admiral Bett that venereal disease was not strictly a war casualty: the incidence per thousand in the British army in France in war-time was relatively low as compared with the peace-time figures. Sir Percy Bassett-Smith, R.N. (ret.), expressed the view that the ratio of venereal disease was not higher in the services than in the civil community. Until notification became compulsory there was little chance of preventing the disease; though public opinion was against compulsory notification, the evident danger arising from the number of people who left the clinics before their cure was complete might be the thin end of the wedge of notification. The Chairman, Sir A. P. Blenkinsop, remarked that the effect of opportunity was strikingly brought out in the Mesopotamian campaign, where the incidence, as compared with other fronts, was low, until the borders of Kurdistan and Persia were reached. In Persia at that time whole populations were in dire necessity, and women were driven to prostitution for the most trifling rewards. If prophylactic outfits were to be continued they must be simplified; the present arrangement was cumbersome and inefficient.

A CO-OPERATIVE CLINIC IN PSYCHIATRY.

At the Court of Governors of the Middlesex Hospital, to be held on November 30th, we understand that the Board will present a report on proposals for co-operation between that institution and St. Luke's Hospital, in the City of London. The object of this working arrangement between a large general hospital and a registered hospital for mental disease is, briefly, to improve the treatment of early mental and functional nervous disorders. The scheme, which has been under discussion for some years, aims at co-operation in respect of funds, material, personnel, and experience in management, and thus at securing greater economy in administration, with more rapid and efficient treatment of the patients. It is proposed to establish two new wards for male and female in-patients at the Middlesex Hospital, where cases will be treated by members of the medical staff of St. Luke's Hospital under the care of its trained mental nurses. In addition a special out-patient clinic will be set up for dealing with border line cases; this, in effect, will constitute a psychiatric section of the neurological department of the Middlesex Hospital. It is hoped that in this way patients with symptoms of early mental disorder will be encouraged to seek prompt treatment and advice. Those admitted to the new psychiatric wards will be on the same footing as ordinary patients in the general wards of the hospital. Patients attending under this scheme will have the advantage of the full resources of a general hospital, and of the services of a staff skilled in the treatment of mental disease; the need for certification may thus be avoided and the prospects of cure improved. We cordially welcome this development of the work of the two institutions; its results will be watched with sympathetic interest by the medical profession. In our issue of September 23rd, at page 577, we mentioned the out-patient clinic in psychiatry which has been established at Cardiff under Dr. Edwin Goodall, by co-operation between the City of Cardiff Mental Hospital and the King Edward VII Hospital. The clinic is held in the out-patient department of the general hospital, but until suitable indoor accommodation is also available this scheme is regarded by Dr. Goodall as incomplete. The success of the Middlesex and St. Luke's scheme in London would no doubt strengthen his hand in pressing for full development of his plan, although it seems a pity that Cardiff, having started so well, should hesitate to make its scheme complete; the hesitation may perhaps be due to the fact that the King Edward VII Hospital is too small for a centre such as Cardiff and cannot be enlarged on its present site. The difficulties of an out-patient mental department without beds are graphically described in a letter by Dr. R. H. Steen, printed at page 998 of our present issue.

THE NOBEL PRIZES, 1921, 1922.

The Nobel Prize for Chemistry for 1921 has been awarded to Professor Frederick Soddy, F.R.S., Lee's Professor of Inorganic and Physical Chemistry, Oxford, whose work on the radioactive elements and on the constitution of the atom is so well known; that for 1922 is awarded to Dr. Francis William Aston, F.R.S., Research Fellow of Trinity College, Cambridge, who has made many important investigations into the electrical discharges in gases and with regard to isotopes. The Nobel Prize for Physics for 1921 has been awarded to Professor Einstein for his work in theoretical physics, especially the discovery of the law of photo-electric effect; and that for 1922 to Professor Niels Bohr of Copenhagen in recognition of his investigations into the structure of atoms. The Nobel Prize for Literature for 1922 has been awarded to Señor Jacinto Benavente, the Spanish dramatist.

On Wednesday next, November 22nd, at 5 p.m., Professor H. C. Jacobaeus, of Stockholm, will give a lecture at the Royal Society of Medicine on the practical importance of thoracoscopy, especially in the pneumothorax treatment of pulmonary tuberculosis. It is understood that he will exhibit the instruments he uses and show some cases.

England and Wales.

LONDON SCHOOL MEDICAL SERVICE.

THE inspecting officers of the Board of Education have made certain criticisms of the school medical service of the London County Council. They have called attention to the need for further administrative supervision at the treatment centres in order that time may not be wasted by failure to supply medical and dental practitioners with a full complement of cases at each session, and to the need for further professional supervision, especially with regard to the administration of anaesthetics, operation treatment for tonsils and adenoids, and dental work. The inspectors state that the skill of those appointed to do operative work and administer anaesthetics at the centres should be in no way inferior to that available in the best managed hospitals. Apart from these criticisms, the inspectors describe the Council's scheme as admirable. In reply, the London Education Committee states that the inspection in 1922 took place at an unfavourable time. During 1921 the centres were full to overflowing, but in 1922, at the time of the inspection, there was a falling off in many areas. Among other reasons for this were the great prevalence of infectious disease and also the unjustified attacks in a section of the public press on throat operations. The Education Committee is addressing itself to the standardization of the qualifications and experience required of medical officers, and has now agreed that for any appointment involving specialist work a tenure of hospital or other appointments affording special opportunities for acquiring experience, or some special academic or post-graduate study or recognized proficiency and experience in the particular capacity for which the service is offered, shall be required. It has also been decided that no surgeon shall be required, as a rule, to operate on more than eight tonsil and adenoid cases per session of two and a half hours (hitherto the number has been ten). The British Medical Association has asked that a clause might be inserted in agreements prohibiting visits to the centres by unauthorized persons, and the Education Committee accordingly has decided that agreements shall provide that no lay person other than the Council's organizer shall be admitted to the consulting room during treatment without the consent of the doctor. The existing agreements provide that the committees of school treatment centres shall, if required by the Council, certify whether a child patient is fit to attend school during the period of treatment; the Education Committee considers that the doctor in attendance at the centre, and not the committee, should so certify. It has also been arranged that a time-book shall be kept at each centre in which the hours of arrival and departure of the medical staff shall be recorded.

BIRKENHEAD MEDICAL SOCIETY.

The annual report of the council of the Birkenhead Medical Society states that there are now on the membership roll the names of 55 members and 2 associated members. During last session the council met four times. Six ordinary meetings were held, at which interesting clinical papers were read and discussions took place, and on one occasion cinematograph films showing bacteria were exhibited. The average attendance was larger than in the previous year. At the annual dinner, held at Birkenhead Town Hall last April, 28 members and 26 guests were present. The following officers and members of council have been elected for the ensuing session: President, Dr. W. A. Pierce; Vice-Presidents, Dr. R. Wyse and Dr. H. Laird Pearson; Honorary Treasurer, Dr. W. A. Pierce; Honorary Secretary, Dr. D. Morley Mathieson; Members of Council, Drs. Fountain Browne, Fardon, Hoeken, Francis Johnston, and Owen. The society was founded in 1856.

TUBERCULOSIS IN BIRMINGHAM.

The report on tuberculosis of the Birmingham Public Health Department states that new cases have been much fewer, the deaths less numerous, and the incidence and mortality among children considerably diminished during the year, both as regards pulmonary and non-pulmonary tuberculosis. There has been a continuous decrease in the number of cases notified and of deaths from tuberculosis since 1913; in that year 5,196 cases were notified, and there were 1,341 deaths—a death rate of 1.53 per thousand, while in 1921 2,247 cases were notified, and there were 1,035 deaths—

a death rate of 1.13 per thousand. As regards preventive measures, the antituberculosis administration in Birmingham is carried out by a staff of fifteen tuberculosis visitors, including a superintendent, and the efforts of this staff are directed, first, to induce the patient to obtain early treatment and to follow out the advice given, and second, to improve some of the general social conditions which tend to spread infection. In regard to the treatment of tuberculosis, at the Broad Street Centre for out-patient treatment a total of 31,204 attendances was made by old and new patients, and 815 new patients attended for treatment. There were 670 beds available for sanatorium and hospital patients, and during the year 2,262 patients were admitted for observation, instruction, treatment, or isolation. At the General Dispensary Tuberculosis Department there was a total of 12,371 attendances for treatment.

Scotland.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS.

THE annual meeting of Fellows of the Royal Faculty of Physicians and Surgeons, Glasgow, took place on November 6th, when office-bearers were appointed as follows: President, Dr. W. G. Dun; Visitor, Dr. W. R. Jaek; Treasurer, Mr. J. Hogg Macdonald; Honorary Librarian, Dr. E. H. L. Oliphant; Connellors, the president, visitor, treasurer, librarian, Dr. James A. Adams (as Faculty representative to the General Medical Council), Mr. Henry Rutherford, Dr. A. K. Chalmers, Mr. J. Mason Noble, Sir Kennedy Dalziel, Dr. A. Freeland Fergus, Mr. A. Ernest Maynard, and Mr. J. Hogarth Pringle.

CHILD WELFARE IN EDINBURGH.

At a meeting of the Edinburgh Town Council on November 2nd a recommendation from the Public Health Committee to close Gogarburn House—a convalescent home associated with the child welfare activities of the council—at the end of the current financial year, was adopted by a large majority. It was stated that the committee had realized that the proper way to treat children between 2 and 5 years of age was not in special institutions. Gogarburn House was intended to house a hundred children, but it had never had more than forty-five, and the expense of each child worked out at £150 a year. It had cost, including the outlay on alterations, something like £10,500; when it was bought an isolation building was found necessary, and for this a hut was bought at a cost of £70, but to convert the hut for the accommodation of children cost over £2,000. It had been found impracticable to treat children up to 2 years of age so far out of reach of the town, the parents, and the doctor as at Gogarburn. If the children were given a fair start in life between the ages of 1 and 2 it was believed that they should not need treatment after the age of 2.

THE CENSUS OF SCOTLAND, 1921: COUNTY OF BUTE.

The county of Bute consists of seven inhabited islands in the lower part of the Firth of Clyde—Bute, Arran, Grent, Cumbrae, Little Cumbrae, Holy Island, Inchmarnock, and the lighthouse islet of Pladda, south of Arran. The whole group is within the most popular holiday region of industrial Scotland, and postponement of the census from April till June has completely vitiated the statistics, alike as to amount of population, its relation to house accommodation, and ages, sex, and occupations. Rothesay, for example, shows an increased population of 63.7 per cent., and Mill shows a 261.5 per cent., whilst in 33,711 of a total enumerated population in the county no less than 13,745 were returned as born in Lanarkshire. All these things being so, it is needless to enter into any details of the contents of the report, excepting, perhaps, to note that 1,453 persons were Gaelic speakers, or 628 less than in 1911. The whole 1,453 were bilingual.

GLASGOW MEDICAL LUNCH CLUB.

At the usual meeting of this club, held on November 9th, Dr. W. L. Reid presiding, Mr. D. M. Cowan, M.P. for the Scottish Universities constituency, was present as the guest of honour. After lunch Mr. Cowan gave a short address, touching on several matters of medical legislation, and impressing on

members the need on the part of lay members of Parliament for guidance from the medical profession on all matters of medical importance. He said that he would welcome some authoritative lead from the profession on all legislation pertaining to medicine. Dr. James Dunlop (Shettleston), in expressing the thanks of the members to Mr. Cowan, assured him that the medical profession in Glasgow would gladly help him in the matter of medical information.

Sydney.

RETIREMENT OF DR. G. E. RENNIE.

UNDER the regulations of the Royal Prince Alfred Hospital, Sydney, fixing the age limit for retirement from the active staff at 60 years, Dr. G. E. Rennie has retired from the position of senior honorary physician and has been appointed on the honorary consulting staff. Dr. Rennie gave a farewell address to the students and the honorary medical staff. He, along with Dr. F. Antill Pockley, who has also recently resigned the lectureship in ophthalmology in the university and the position of senior ophthalmic surgeon to the hospital, were entertained at a complimentary dinner by the members of the honorary medical staff.

INDUSTRIAL HYGIENE.

At the invitation of the industrial department of the National Y.W.C.A. the welfare nurses employed in business houses in Sydney recently heard an address from Dr. Lanza, the Commonwealth expert in industrial hygiene. He first sketched briefly the development of industrial hygiene work, beginning with the effort at accident prevention. The next step was in regard to dangerous occupations, such as those involving the risk of phosphorus or lead poisoning. After a time it became evident that there were problems of health not so clearly defined as accidents and occupational diseases but yet involving an economic loss to the community. The employment of the trained nurse in the industrial plant had been a great step forward. The work of the nurse at the dispensary was much more than attention to minor accidents—it was preventive work and was of great value from the business as well as the human point of view. He emphasized the necessity of the nurse keeping proper records of all cases treated, showing the nature of the injury, the amount of time lost, and the department from which the patient came. In this way it was possible to compute how much time was lost to business. A run of some particular ailment in one department might point to some defective condition in it, such as the lighting. Dealing more especially with the industrial prospects of Australia, he said that the natural development of industry in a country so largely wool-producing would be in the direction of an increasingly large number of women workers. While there was a variety of opinions as to the effect of industrial conditions on the health of women, there was not much accurate information; it was necessary, therefore, that those who were working in plants employing women should keep accurate records if any scientific conclusions were to be reached. As an illustration of the value of deductions to be made from such records he spoke of one firm which had experienced heavy loss in selling silk reels because of bad matching. The health department on investigating this matter found that headaches were common among the employees, and that these were due to defective eyesight. Under appropriate treatment with glasses the trouble disappeared and the firm's loss also ceased.

PROPOSED CANCER HOME.

It is proposed to build a home for cancer patients in the grounds of the Home for Incurables at Ryde, near Sydney. The urgent necessity for some accommodation for patients suffering from cancer has long been recognized, but the authorities of the Home have not been able to accommodate these cases. Plans for the proposed institution are now being prepared. It is estimated that the building will cost £27,000, and of this amount £23,000 is already in hand. The necessity for this home is obvious from the striking figures quoted by the Government statistician. During the years 1914-20 more patients died from cancer and other malignant growths than were killed in several of the spectacular battles on the Somme, the total for seven years for the whole of Australia being 28,556. The statistician points out that the male death rates from cancer in 1920 were in excess of those from tuber-

culosis in all the States except Western Australia, while the female deaths from cancer were in excess in all the States. While the death rates from tuberculosis show a general tendency to decrease, the death rates from cancer display an increase in nearly every recent year.

Attention was directed to the question of the increase in cancer and the reported advances made in its treatment by x rays by a question asked in the Legislative Assembly by Dr. Richard Arthur: "In view of the favourable reports of medical authorities that cures of cancer can be effected, and other forms alleviated, by the use of x rays, will the Minister of Health consult with the experts with a view to securing a modern x ray plant, and place the necessary sum on the estimates for this purpose?" The Minister agreed to adopt this course.

Correspondence.

INSULIN AND DIABETES.

SIR,—In connexion with Professor J. J. R. Macleod's interesting article on insulin and diabetes, and the difficulties of manufacture arising from the circumstance that the trypsin of the pancreas attacks and destroys the insulin, I may perhaps suggest to those working on this subject that the trypsin might be neutralized and got out of the way by pounding up the pancreas in serum.

I have elsewhere¹ drawn attention to the relevant fact that the erosion of the abdominal walls by tryptic ferment, which is so great a source of misery in duodenal fistula, can be very easily and effectively combated by calling in to our aid the antitryptic powers of the serum—in other words, by applying lint soaked in normal horse serum.—I am, etc.,

London, W., Nov. 11th.

ALMROTH E. WRIGHT.

SIR,—It has been known for some time that the injection of a fresh extract of the pancreas reduces the sugar content of the blood in normal animals, and on this point the experiments quoted by Dr. Thomson² confirm the observations Heward, Forsyth, and I published in 1921.³ For a much longer time it has been recognized that such injections temporarily improve the glycosuria and hyperglycaemia following pancreaticectomy, but numerous attempts to apply this knowledge clinically to the treatment of diabetes have ultimately ended in failure, in spite of an ephemeral success in some instances.

The most satisfactory results appear to have been obtained by Zuelzer and his associates,⁴ who employed an expressed extract of the gland treated with alcohol. Six cases were given injections of this preparation, and the effects were reported to be uniform and constant, the sugar, acetone, and aceto-acetic acid always diminishing and usually disappearing from the urine in two to three days. The after-history of these cases has not been reported, nor have further successes been claimed for the treatment. Later Porschbach, employing the same method,⁵ obtained similar results with depancreatized dogs, but was not so fortunate with human diabetes, for, although he found a temporary reduction in the glycosuria, the acetone excretion was not affected, the temperature was raised, and other serious symptoms developed.

The main point in which the earlier work of the experimenters in Macleod's laboratory differed from that of previous observers appeared to be that they had succeeded in devising a method of preparing an extract of the islands of Langerhans, free from the digestive ferments of the pancreas, by making use of Schulze's observation that ligation of the ducts leads to degeneration of the glandular acini, while the cell islets remain intact, and later by taking advantage of Ibrahim's statement that the foetal pancreas is almost free from proteolytic enzymes. Now, however, they seem to have abandoned these procedures and reverted, more or less, to the methods previously adopted by Zuelzer and Scott, using the whole pancreas of the full-grown ox and alcohol as a means for removing the protein and digestive ferments. The strict propriety of the name "insulin" for this preparation is therefore open to question.

As was the case with Zuelzer's, and later with Scott's, preparation, the extract now being used by the Toronto workers gives encouraging results with depancreatized

⁴ Zeit. f. ex.

⁵ Deut. med. Wochenschr., 1922.

animals, but I am quite in agreement with Dr. Thomson when he says it is doubtful "whether the condition of animals after that operation is exactly equivalent to the extraordinary variety of conditions in man which are collected under the name diabetes." My experience with the methods of differential diagnosis that I and my fellow workers have recently elaborated has suggested that insufficiency of the internal secretion of the pancreas is the dominant factor in less than half the cases of glycosuria met with in practice in this country, and one would therefore expect that "insulin" would be useful in some such proportion of diabetics, but as it must be administered intravenously or subcutaneously, and the effects are transient, it is evident that it is not a method of treatment to be lightly undertaken or that can be continued indefinitely. As yet the clinical data are too scanty for a definite conclusion to be reached, but so far as can be seen at present it seems likely, as Macleod himself has said,¹ that insulin will be chiefly of value in tiding patients over those crises which are frequently uncontrollable by other means. It is advisable that stress should be laid upon this statement in view of the optimistic forecasts as to its curative properties which have been so widely circulated in the press recently, thereby raising exaggerated hopes, which are not likely to be fulfilled, in the minds of many diabetics.—I am, etc.,

London, W., Nov. 11th.

P. J. CAMMIDGE.

THE TREATMENT OF ACUTE SALPINGITIS.

SIR,—After reading the paper by Dr. Campbell on the treatment of salpingo-oophoritis and the discussion thereon at the Annual Meeting of the British Medical Association, reported in your issue of October 14th, I was surprised that no mention was made of treatment of acute suppurative salpingitis by salpingostomy—that is, a complete laying open of the tube from the abdominal ostium to the uterine cornu, followed by drainage of the pelvic cavity for a variable number of days. So crude a procedure as the removal of the suppurating tube is advocated by Dr. Campbell at the earliest possible moment, apparently on the baseless analogy drawn between suppurative inflammations of the tube and appendix. The reasoning is that apparently both tube and appendix have something of the same gross appearance, both are liable to contain pus, and both may cause a varying degree of peritonitis, therefore why should not the suppurating tube be treated in exactly the same manner as an appendix in a similar condition? There is so patent a confusion of thought in this reasoning that some of those who took part in the meeting assumed that Dr. Campbell had put forth his thesis chiefly in order to provoke a discussion which otherwise might have languished. But in his closing remarks Dr. Campbell is reported as having maintained his ideas of the analogy of the appendix and the tube, and we must therefore accept his views of treatment as his considered judgement.

To my mind the analogy breaks down when we remember the fundamental differences in bacteriology and morbid anatomy of inflammation of the appendix and the tube and in the clinical differences and dangers of the two diseases. In the one case is a virulent combination of streptococcus and *B. coli* derived from the bowel, liable, as we know, to set up a rapidly disseminated general suppurative peritonitis, usually fatal; while in the second case the organism is ordinarily the gonococcus (except in puerperal cases, when the streptococcus is often present in addition), a microbe of much less danger to the peritoneum, and seldom the cause of a spreading peritonitis. The perforated appendix is virtually of the same order of lesion as the perforated colon, for by its rupture it liberates the same organisms into the peritoneum—an accident of the greatest potential danger.

Moreover, the appendix is situated in the abdominal cavity proper, while the tube leaks its pus into the depth of the pelvic cavity (puerperal cases excepted), where it is in the large majority entirely shut off from general dissemination.

Treatment of the acutely suppurating tube, therefore, is seldom required for an extending general peritonitis, but should be designed with these objects:

1. To prevent the persistence of a chronic pelvic peritonitis, and to interstalt salpingitis.
2. To prevent the formation of a pyosalpinx.
3. To preserve the patient's chances of future child-bearing.

Removal of the tubes will ensure the first two conditions provided the ovary is not infected, but it will condemn a woman, frequently young and recently married, to a life of sterility.

Salpingectomy is an unnecessarily harsh treatment, and, in my opinion, should not be practised unless the tube has been previously damaged beyond functional repair by former attacks of inflammation. For a first attack complete salpingostomy is a more rational form of treatment of the tube. First, by affording wide evacuation of pus along the whole lumen, it allows resolution of the tube wall, rapidly restoring it to a condition indistinguishable from the normal slit tube (as proved in one of my own cases at a subsequent *post-mortem* examination following death from pneumonia); secondly, the formation of a pyosalpinx is obviously impossible; and, thirdly, the tube, after full resolution, is able to function again as a gutter along which ova can be conveyed to the uterus.

The greater number of cases of salpingitis are mild enough to escape operation, but where I join issue with Dr. Campbell is that, having opened the abdomen, salpingostomy is a more rational mode of dealing with the tube than salpingectomy.—I am, etc.,

London, W., Oct. 31st.

ALECK W. BOURNE.

PSYCHO-ANALYSIS.

SIR,—The leading article in your issue of November 11th tempts me to urge the foundation of a special institution for psycho-analysis—call it hospital or clinic or what you will.

To your readers facts about my work may be of little interest, but at the risk of being egotistical, I feel I must give them as they are not hearsay evidence, and I believe can be confirmed by the experience of others.

At King's College Hospital, Denmark Hill, I have an out-patient department for mental diseases. The following patients have consulted me:

A young man who has, as the principal symptom, the fear that he will swallow one of his buttons. At frequent intervals during the day the unfortunate youth is compelled to count each button on his clothing lest, perchance, one may be missing, and he may have swallowed it. He is virtually a prisoner, as he cannot even go into the tiny garden at the back of the house for fear he may swallow a fly, or spider, or something else.

A young girl has an uncontrollable impulse to walk to the left. Examination by experts in other departments can find no physical basis for this symptom.

A young girl has auditory hallucinations recognized by herself as hallucinatory. The "voices" are very disgusting and cause her much distress.

A man has irrepressible blasphemous thoughts which he hates and which interfere with the proper discharge of his duties. Another has loss of memory for a definite period of his life extending over years. Then there are the cases of anxiety neurosis—a numerous class.

These are only a few illustrations out of many. I wonder if the majority of your readers realize the unhappy plight of these unfortunate people. Their sufferings are intense. In most cases all social life is impossible for them and in severe instances they are unable to engage in any occupation. What is to be done? Treatment on ordinary medical lines is useless in my experience. With the help of several enthusiastic students I am able to give therapeutic conversations and other psycho-therapeutic measures with a certain amount of benefit. These procedures are not to be confused with a course of psycho-analysis and are of value only in early cases. But my time is limited, numerous other cases await my attention, and I personally cannot undertake a true psycho-analysis.

Attached to the Neurological Clinic and my own is a department for psycho-therapy. The officer in charge has recently resigned, and his successor has not yet been appointed. So I can speak impersonally when I say that even he cannot be expected to give the time required for a full analysis of all the cases which could be sent to him.

Many of these cases also need in-patient treatment. They require rest and removal from domestic worries and injudicious relatives. The mental hospital is not the place for them. They are not insane in the ordinary sense of the word. No general or special neurological hospital will receive them. The Maudsley Hospital may help, but I fear will soon be filled with early cases of the psychoses. The only thing to be done, therefore, is to found a special hospital with out-patient clinic.

It should be staffed with whole-time, well-paid, and comparatively numerous medical officers. Specialists of all kinds should be attached for consultations. Other details are unnecessary for the moment. The advantages of such an institution would be many: I name a few as illustrations. Cases such as I have instanced would receive proper treatment.

Extensive study could be made upon them and results and details could be published in a manner which is not possible in the case of private practice. Research work on the lines indicated by your leading article could be undertaken, and it would afford a splendid opportunity for post-graduate teaching.

Where is the money to be found? I have no doubt that the public would provide the money if the profession were to endorse such a scheme. The first thing is to convert the medical profession. Hence this letter.—I am, etc.,

R. H. STEEN.

City of London Mental Hospital, Dartford, Kent,
Nov. 13th.

SIR,—I was astonished to find from Dr. Steen's letter (November 4th, p. 894) that he apparently believes that thought can occur without physiological nerve and brain activity, and that he considers belief in the latter to be demoralizing. Thus he would condemn every scientist who uses it as a working hypothesis as demoralized. He then recommends the anxious inquirer to study Dr. Hart's "little book" in which he himself has such implicit faith. This seems to me very much like suggesting a Sunday school tract as a serious contribution to a discussion on some abstruse problem in exegesis, for I can find nothing either in Dr. Steen's letters or Dr. Hart's book to justify faith in what the writer of your excellent leading article has called "the diagnostic tools" of the psycho-analysts. The question of suggestion has been ably dealt with by Dr. Elder. To respond with a direct negative in no way disposes of it.

Throughout Dr. Steen seems to reject that which according to knowledge and analogy is probable and to accept that which is so improbable as to require much to be taken on trust in order to make it appear conceivably possible. Under these circumstances it is surprising to find your correspondent indulging in cheap sarcasm with regard to the former. In the third paragraph of his letter there is something remarkably like an attempt to avoid the main issue if not to sidetrack it.

Dr. Steen is good enough to ask for suggestions as to literature. In all seriousness I would recommend a study of psychology—such works, for instance, as *Psychology from the Standpoint of the Behaviorist* by John B. Watson, *Human Psychology* by Howard Warren, and *Human Behaviour* by Stewart Paton. In the last he will find the following sentence: "We now know that there are no specific differences of kind but only those of degree between the reflex activities of the protozoa and the highest mental processes of man." The perusal of such works will show Dr. Steen that psychological problems can be studied by the aid of physiology and logic. Assumptions, assertions, and sarcasm may have their uses, but are out of place in scientific controversy.—I am, etc.,

Harrogate, Nov. 12th.

P. McBRIDE.

SIR,—In connexion with the correspondence in your columns on psycho-analysis I trust you may find room for this (the first) intimation of a discovery on the subject of dreams which you may agree to be of epoch-making importance—or you may not.

The origin was very simple. I dreamt that the newspaper had not come; and where this might have led I cannot say, but—perhaps fortunately for the future of psychology—I awoke, and my thoughts turned at once to the interpretation of the dream. The thing seemed so simple and apparently so innocent that I knew from my Freud it could only refer to some gross and coarse erotic desire, of a nature so base that I could only be thankful that I was unable to recognize it; and I knew that it remained unsatisfied, for otherwise it could not have caused my dream. But I soon became conscious of mental conflict, and I lay awake and thought. Was Freud right? Of course he was—no, he wasn't. Was I really of so base a nature? Of course I was—no, I wasn't. Ever-increasing conflict. The strain became almost intolerable, and might well have upset better balanced minds than mine when—unexpectedly, mercifully—the conflict was resolved, not by the discovery of the sub-consciously desired orgy, but by the recognition of a truth which underlies, and incidentally both confirms and the opposite (upsets), all that Freud has taught. For I had interpreted my dream—and, as a necessary corollary, a sense of peace came over me. "The newspaper had not arrived!" At last I knew what it meant, and my conviction became

complete when the maid came in with my early cup of tea—it meant that I wanted my breakfast.

From this simple explanation of this simple dream emerges a new theory of dreams, based on the work of Freud, but going deeper and incriminating the most primitive of all instincts. Obviously all dreams refer to food and to the desire for food—an instinct more all-prevailing and, to some natures at least, more frequent even than that of erotic desire.

A few of my deductions will show how completely this theory explains all dreams. All newspapers refer to breakfast, or the opposite (evening papers). All very hard objects are either bones or oyster shells (inedible) or the opposite (soft, inedible—for example, sand). All soft objects are puddings or, if very soft, soufflés—or the opposite (not soufflés). An india-rubber ball is clearly gristle (can be chewed but not swallowed) or the opposite (must be swallowed—conflict; for example, party with all eyes on the gristle-chewer). All colours I find refer to drinks—for example, yellow stands for beer, or the opposite (not beer—conflict); while green stands for undrinkable things generally (accepted—no conflict), or the opposite (Chartreuse; idea again accepted—no conflict). All rhythmic movements—riding, organ-grinding, the treadmill, etc.—obviously refer to mastication, and children who grind their teeth at night have greedy natures, or the opposite (ungreedy natures); and so have we all, if we will only be honest with ourselves.

But I take up too much of your space. Anyone can elaborate the theme to suit his fancy. As I desire to avoid an overwhelming correspondence, I beg to subscribe myself—Obediently yours,

October 31st.

A. DREAMER.

LILLIPUTIAN HALLUCINATIONS.

SIR,—The attention called to the above syndrome in the *EPRHOM* (November 4th, 1922, No. 331) is of interest because of its rarity and the fact that it has so far received little notice in the textbooks and literature, and, therefore, the following case of a bedridden old lady may be worth recording.

Mentally she was exceedingly clear in every other respect, but she used to describe to me most vividly pictures of hosts of very little people who appeared to her to be working upon buildings, fortresses, etc., all within the range of her own small room, the operations apparently taking place around and about the foot of the bed, and the furniture. She was generally quite interested in watching and describing their work, hundreds being employed and miniature horses and wagons used to haul timber and stone, and she would enter into details as to the way they were dressed and harnessed. Some of the figures apparently worried her a little because they ranged themselves just outside the window and gazed at her as she lay in bed, but it was not until some visiting ecclesiastical tactlessly told her that they were "bad angels come to punish her for her sins" that they seriously upset her, and it took considerable time and effort to dislodge this wicked suggestion from interfering with her otherwise peaceful serenity.

Her descriptions conjured up scenes similar to those met with in *Gulliver's Travels*, though I doubt very much whether she had ever read, or even heard, of Swift's inhabitants of Lilliput.—I am, etc.,

Lichfield, Nov. 4th.

F. M. ROWLAND, M.D.

SERUM BY THE MOUTH.

SIR,—In the *JOURNAL* of October 14th Dr. D. Montgomerie Paton of Melbourne states that I used serums orally in 1892, and adds "where Dr. Allison admits he still is my work begins." I, however, am hardly where I was in 1892, my statement being: "I think 5,000 units of (antidiphtheria) serum more powerful in this way (raising body resistance) than 20,000 units of any other variety. Why I do not know, but it cannot be the horse serum (that is, the common basis) *per se*."

If Dr. Paton can tell me I shall be glad. And perhaps I may be allowed to use, Mr. Editor, some words of your own, as uttered in the *JOURNAL* of October 28th in this connexion:

"Whether it be the chemist observing an unexpected precipitate, or an astronomer measuring the variability of a star, the new phenomenon must be accurately recorded and verified before the explanation is sought. The observation of the effect must precede the cause; the existence of a problem must come before its solution can be considered."

And it often requires, I think, different types of minds to make the whole of a problem complete. The experimental mind makes the experiment; the observing mind notes the occurrence; the analytical mind seeks the explanation. But the observation precedes and causes the explanation.

The work of Sir Patrick Manson is deservedly honoured, but has the Pernivian (?) medicine man who discovered cinchona bark and the treatment of malaria had his fair share of recognition? And of the two—Manson or medicine man—which was really the greater human benefactor? Malaria (its hot stage preventing sweating, which means torture in the tropics) was the problem, the mosquito was its solution, but quinine was its cure. And the malaria and quinine came first.

And so in a less degree with serums and vaccines orally. The administration comes first and causes the explanation, which comes later. Only the observation is not where it was in 1892, because it has been extended by the giving of anti-diphtheria serum orally in follicular tonsillitis, pneumonia, and influenza. In doing so I think I have proved that this serum is not specific for diphtheria alone, but that it is a specific (and a potent one) in raising the resistance of the body to diseases other than diphtheria.

Whilst the practical results appeal to me far more than the explanation, if Dr. Paton, in *New Serum Therapy*, can say why the effects of anti-diphtheria serum are so much better than other serums, I shall be very pleased to have the explanation, because it may mean that others will try the oral methods and the extended use of this valuable remedy. And this will be to the common good, as in my opinion the oral method reduces the incidence of anaphylaxis and other drawbacks of the hypodermic method, the dosage being the same.—I am, etc.,

T. M. ALLISON, M.D.,

Honorary Physician to the Wingrove Hospital,
Newcastle-upon-Tyne.

November 4th.

P.S.—Since this was written there has been published in the *EPITOME* of November 11th a note showing that the oral administration of vaccines is exciting interest abroad. The note states that Nicolle and Conseil have brought forward evidence in favour of the efficacy of this method in Malta fever and bacillary dysentery.

ETIOLOGY OF RICKETS.

SIR,—The interesting discussion on the causation of rickets in the *BRITISH MEDICAL JOURNAL* of November 4th (p. 846) must appeal to many general practitioners. As one of them, I may be permitted to offer a few observations on the disease.

There are, I suggest, two factors, and only two, concerned in its causation: (1) the state of the air the child breathes—the air factor; and (2) the kind of food the child is fed on—the food factor. Both these factors act and interact, so that it is, in some cases, not easy to determine the predominating factor. I believe in the vast majority of cases of rickets the air factor is the predominating one. A father and mother, belonging to the poorer paid members of the working class, live in a kitchen with four or more children. The window is closed; likewise the door of the apartment. These are the ideal conditions for breeding rickets. And here, in accordance with the theory involved, it is not usually the first born that suffers from rickets. It is the "late arrivals" on whom the brunt of the disease falls. It is, in my opinion, the poisoned state of the air the child breathes that is the great factor in developing the disease. It does not necessarily follow that rickets is due to a defective supply of oxygen, although if the kitchen window is kept open for three or four inches by night and by day the disease will, as in the cases I have watched, probably become arrested.

The early symptom of rickets is sweating about the head, especially at night; the hair in consequence becomes matted. Although convulsions in childhood are generally ascribed to the cutting of teeth, indigestion, etc., I think there is usually a rickety basis. My belief is now so strong that I go so far as to tell the mothers of children who have fits that if they will keep the window open night and day their child will never have a fit.

I am not so competent to discuss the food factor. But my daughter, in the early months of her life, was fed on pasteurized milk. She developed signs of rickets, sweating about the head, and a tendency to inner curves of the tibiae.

There was nothing for it than to put her back on plain cow's milk and run the risk of bovine or other infection. The signs of rickets disappeared, but the tonsils and the adenoid tissue in the roof of the pharynx became infected. I have little doubt that these disorders are due to bovine infection.—I am, etc.,

Glasgow, Nov. 6th.

JOHN T. MACLACHLAN, M.D.

SIR,—I have been reading the discussion on the etiology of rickets in the *JOURNAL* of November 4th with great interest, and cannot believe it is a disease due entirely to faults in diet. I was in charge of the Madras Maternity Hospital for some years, and over 20,000 patients passed through my hands, and I can recall no case of a truly rachitic pelvis. There were numbers of cases of flattened pelvis, and this we attributed to the habit of children and young adults of carrying heavy pots of water on their heads. A few of the higher caste Brahmin and Goshia Mohammedan women came as inmates. The rest of our patients consisted of Europeans, Europeans, Mohammedans, and Hindus, the last largely predominating.

The diet of the poor in South India consists of raggi, cumbu, or cholam, with a few pieces of meat in the curry at night, now and again. Rice is not the staple diet of the native of the south, as pointed out years ago by the late Surgeon General Cornish, C.I.E.—rice to the poor is a luxury. Ghee (clarified butter) or gungelly oil are used in cooking. Buttermilk is occasionally drunk.

Children run about in the sun as soon as they can toddle, and are naked except for a string round their middle. They take the breast up to 3 years of age, and are dosed almost daily with castor oil. In the *Indian Medical Gazette* I used to read the reports of the midwifery hospitals in the north of India, and the number of operations required on account of rachitic pelvis was large. I cannot certify the diet of the poor in the north, but bajri—a millet—seems the staple article; moreover, they eat chapatties, made of unleavened flour and ghee, which are not used in the south. The diet in the north is as nourishing or more so than in the south; in the latter rickets is unknown, whereas in the former it is a common complaint. In the south it is never cool; in the north frost prevails; the sun is, however, hot. In Iceland rickets is stated to be unknown.

Surely there is something more than diet to account for such a discrepancy. Most diseases nowadays are due to microbes or infection—why not rickets?—I am, etc.,

A. J. STURMER,

Lieutenant-Colonel I.M.S. (ret.).

Clifton, Bristol, Nov. 7th.

TREATMENT OF FEVER.

SIR,—In your issue of June 4th, 1921 (p. 835), you were good enough to publish a letter from one of us on the treatment of toxæmia by means of the following complex:

Asphid	gr. x.
Phenacetin	gr. v.
Pulv. ipecac. co.	gr. v.

It was suggested that in febrile diseases the sweat centre is paralysed by the toxins (hence the dry skin), that toxins are eliminated by the sweat (hence the moist skin which accompanies recovery), and that the complex tends, without producing ill effects, to restore the centre to action. Since then the treatment has been extensively tested with very considerable success in a number of acute febrile diseases—measles, pneumonia, diphtheria, erysipelas, puerperal fever and sepsis generally, inflammation and threatened abscess (before pus formation), and the like. Even in pyorrhoea it gives quick but only temporary relief. The action in erysipelas is typical and striking. If given early and continued day by day, the guide being the temperature, the inflammation will be reduced at the site of origin, commonly within twenty-four hours, and the patient will declare himself much relieved; but there will be a ring of inflammation, somewhat narrow and faint (comparable to the ring in ringworm), round the original site. Next day the ring will have retreated farther and be fainter, and so on, day by day. About the fifth or sixth day the patient will have recovered.

The almost invariable result of this treatment in acute disease is sweating, fall of temperature, and immediate relief from pain and feelings of illness. The signs and symptoms may, commonly do, recur; but they can be reduced again and again. In any case, the illness tends to run a short course of

reduced severity. A more extended statement is in preparation. Meanwhile we have had no opportunities of trying the treatment in small-pox. May we appeal for help to your readers, and express the hope that they will publish their results? Our hopes, we may almost say expectations, are that, if the treatment be employed early in the disease, vesication may be prevented; or, if not vesication, pustulation; or if not the prevention of pustulation, at least a mild attack may be secured.—We are, etc.,

R. J. G. PARNELL, Surg. Comdr. R.N.
STEPHEN GREEN, M.B., Ch.B., D.P.H.
G. ARCHDALL REID, M.B., C.M.

Southsea, Nov. 7th.

THE OUTBREAK OF SMALL-POX AT POPLAR WORKHOUSE.

SIR,—I have read with interest your report on the above outbreak appearing in the BRITISH MEDICAL JOURNAL for this week. In many ways the outbreak appears to resemble closely the one which occurred in the Mile End Infirmary in 1911. That outbreak originated in an overlooked case, a girl of 12, who was allowed to remain unisolated in the institution until the occurrence of secondary cases revealed the true nature of her illness. The outbreak resulted in nearly 70 cases, 10 of which proved fatal. In the press reports of the outbreak, although the neglect of vaccination in the East End of London was emphasized as a cause of the outbreak, no mention was made as to the vaccinal condition of the unrecognized case, who as a matter of fact was a vaccinated child.

In the present outbreak at Poplar also no mention is made in your report as to the vaccinal condition of the patient whose overlooked attack is responsible for the outbreak. Judging by past experience I think we may conclude that he had been vaccinated. It is unlikely, had he been unvaccinated, that his attack would have been unrecognized. I feel fairly confident, therefore, in surmising that he had been vaccinated, and, if this is so, it will be interesting to learn whether his attack was one of those modified attacks which so often occur in vaccinated subjects, and in which diagnosis is so difficult that mistakes easily occur and cause so much mischief by spreading the disease.—I am, etc.,

Town Hall, Leicester, Nov. 13th.

C. KILLICK MILLARD.

THE WHITE MAN IN THE TROPICS.

SIR,—In your article, "The Place of the White Man in the Tropics," you make some statements which do not seem sufficiently explicit. I have not read Dr. Hewetson's paper, but most of the points reproduced by you will be readily understood by anybody with a knowledge of the tropics, though I prefer to think that a more limited indulgence in "cocktails" and such-like and a better appreciation of the fitness of things will win for the tropics a more favourable reputation.

Your article seems to suggest that both the coloured and the white races appeared on the face of this earth at the same time, and that the coloured races were in the tropics or migrated to that region to suit their colour. This idea conflicts with the long accepted theory that pigmentation is a response of Nature to the heat of the sun—an adaptive modification so commonly seen in the animal world.

Not long ago Sir Arthur Keith, doubtless working on these lines, elaborated the pigmentation theory. He was of the opinion that at first all were white people, and that the colour of the tropical man was due originally to a mild chronic affection of the suprarenals caused by the tropical conditions, and that subsequently the system acquired a habit of constantly producing the pigment. This theory of resultant pigmentation gains support from the historic fact that both the Hindu and the Anglo-Saxon are of the same Aryan family, their present differences being probably due to the climatic conditions of the parts they migrated to.

If evolution, ethnology, and the pigmentation theory, with—if you will—Keith's elaboration of it, be accepted, one wonders why now the white man should not be able to live and colonize permanently in the tropics if he will live a sober and regulated life. I do not mean that the physical qualities of the offspring in the tropics must or will necessarily be the same as his ancestors; but is that not a detail?—I am, etc.,

London, Nov. 4th.

A. ANNESLEY GOMES, F.R.C.S.

* * * Far be it from us to pretend to settle, in the course of a paragraph, the vexed question of the origin of the races of man. Though some respectable authorities have held the contrary opinion, it is perhaps probable that all races are

derived from a single ancestral stock, but if so the separation of the several races now existing must have occurred so far "in the dark-backward and abysms of Time," that we may properly regard the white man, the yellow man, and the negro as aboriginal.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

SIR,—I deplore the relaxation of the Regulations as affected by the repeal of By-law CXIV. I am of opinion that "the honour and dignity" of the College will be impaired thereby, and that the proofs of "general culture" as at present required will be lowered. In order to counteract this tendency I submit that exemptions to candidates over 40 years of age should be abolished, and that no candidate should be admitted to examination under 30 years of age; also that the examinations in languages should apply to all candidates, and that especially the examinations in Latin and Greek should be expanded, made more comprehensive and more thorough. Membership of the College is now rightly regarded as the professional and educational passport to the Fellowship; therefore the general standard should be raised, especially in view of the new by-law.—I am, etc.,

November 10th.

M.R.C.P.

DERMATITIS AMONGST CEMENT WORKERS.

SIR,—With reference to the letter from Dr. S. Norman Dykes, published in the BRITISH MEDICAL JOURNAL of October 28th, the following case may be of interest:

J. T., a man aged 38, describing himself as a plasterer's labourer, consulted me in February, 1921, for a desquamating rash, limited to a few spots on the arms and hands. I saw him only once then, and gave him arsenic internally and calamine ointment, which apparently cleared the condition up. I saw him again in September, 1921, when the condition had recurred more extensively, with much itching. I then treated him with a lotion containing lead, tar, and glycerin, but he was back again in November worse than ever. In December I certified him unfit for work, when the condition rapidly cleared up. In April, 1922, he came again, with both hands and forearms completely covered with a profusely exfoliating eczema, similar to that described by Dr. Dykes. This proved very obstinate. Of a variety of lotions and ointments which I tried, I think it improved most with mug. terr. "Fuller's." It has gradually cleared up, but the man is still unfit for work. He told me that his work was chiefly with cement, and that several other men working with him were similarly affected to a less degree.

Perhaps the most interesting feature of the case, regarding it as an occupational disease, lies in the fact that the patient was successful in securing compensation under the Workmen's Compensation Act. His approved society took it up, as I was prepared to certify that I considered the condition due to the man's work, and apparently the employer's insurance company did not make any difficulty about paying compensation. At all events the case did not go to court. This leads me to believe that these are not isolated instances, and that we must recognize cement as a cause of occupational eczema.—I am, etc.,

York, Oct. 31st.

J. C. LYTH.

ALOPECIA AREATA AND STRABISMUS.

SIR,—I have read with much interest the comments made by Dr. Charles F. Harford, in his letter of September 30th, and by Dr. W. Inman, in his letter of November 4th, upon my paper, "Alopecia areata and strabismus," contributed to the proceedings of the Dermatological Section at the recent Annual Meeting. I hope to make, at an early date, the further investigations suggested by Dr. Inman.—I am, etc.,

Glasgow, Nov. 12th.

J. GOODWIN TOMKINSON.

Universities and Colleges.

UNIVERSITY OF OXFORD.

THE gift of £100,000, made in accordance with the will of Sir William Dunn for the establishment of a school of pathology at Oxford, will be formally reported to a congregation next week, when a proposal to allocate a site in the parks will be made. The gift is subject to the condition that the University shall provide a provision for the upkeep of the chair of histology staff. The school is to be known as the school of Pathology. The trustees have adaptation of the existing department of pathology for the school of pharmacology.

UNIVERSITY OF LONDON.

Graham Scholarship in Pathology.—As announced in our advertisement columns, applications for the Graham Scholarship in Pathology must be received by the Principal Officer of the University of London, South Kensington, S.W.7, not later than by the

at post on January 1st, 1923. The scholarship, which is of the value of £300 per annum tenable for two years, was founded under the will of the late Dr. Charles Graham, to enable "a young man to continue his pathological researches and at the same time to secure services to the School of Advanced Medical Studies connected with the University College Hospital as a teacher under the direction of the Professor of Pathology."

UNIVERSITY OF GLASGOW.

The following degrees were conferred on November 11th:

M.D.—John Stewart (with commendation).

M.B., Ch.D.—W. Morison, G. J. Muller.

UNIVERSITY OF DUBLIN.

The following candidates have been approved at the examinations indicated:

FINAL M.B., PART I.—Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene; Pathology and Bacteriology: H. F. J. Henry, L. C. Brough, J. B. Bradshaw, M. A. Gerrard, G. A. Sloan, H. E. Mooney, S. Wiggles, D. R. R. K. Carson, R. L. C. Proctor, P. V. Duke, I. J. Inneson.

Dorothea J. Booth, P. B. Robinson, L. M. Whitlitt, J. S. Armstrong, L. MacS. Bell, S. Narinsky, W. A. Richmond, P. P. Van der Merwe, J. P. Stokes, Lucy R. R. Pigott, H. W. Strong. **Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene, in completion:** W. L. W. Smith. **Pathology and Bacteriology, in completion:** S. McDermott, Gladys Weatherill, A. V. D. Crawford. **Materia Medica and Therapeutics, Medical Jurisprudence and Hygiene only:** J. D. Beatty, J. L. Livingston, C. Lord-Flood, J. Craig, P. C. de Plessis. **Materia Medica and Therapeutics; Pathology and Bacteriology only:** J. L. Marshall, A. Hawthorne. **Medical Jurisprudence and Hygiene; Pathology and Bacteriology only:** P. D. Plei. **Medical Jurisprudence and Hygiene only:** H. Mincey.

D.P.H., PART I.—Chemistry, Bacteriology, Physics, and Meteorology: T. F. Wilson.

DIPLOMA IN GYNAECOLOGY AND OBSTETRICS.—H. S. Jacobs.

* Passed on high marks.

NATIONAL UNIVERSITY OF IRELAND.

At a recent meeting of the Senate the following, among other awards, were made:

Medical Travelling Studentship (Pathology).—Thosbald W. T. Dillon, B. B. Ch., University College, Dublin.

Dr. Henry Hutchinson Stewart Medical Scholarship.—Physiology: Thosbald W. T. Dillon, University College, Galway; **Anatomy:** John O'Driscoll, University College, Dublin.

The Senate decided that the conferring fee for all Bachelors' and Masters' Degrees should be £5 (except in the case of medicine and dentistry, the conferring fees for which should remain unchanged).

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

At an ordinary meeting of the Council was held on November 9th, when Sir Anthony Bowly, President, was in the chair.

Issue of Diplomas.—Diplomas of membership were issued to the candidates found qualified at the recent examinations. (The names are printed in our report of the council of the Royal College of Physicians, published in our issue of November 4th, p. 894.)

Alterations in the Regulations for the Conjoint Degree.—These, which have been approved also by the Royal College of Physicians, will come into force, and be applicable to candidates who have not satisfied the required preliminary examination in general education before January 1st, 1923.

The President reported that Mr. K. M. G. Bailey had been elected a Stratford research scholar, and that Sir John Lynn-Thomson had been appointed a member of the Advisory Board of Medicine at the University of Wales.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

At a meeting of the Royal College of Physicians of Edinburgh, held on November 7th, Sir Robert Philip, President, in the chair, Mr. Currie, H. A. Foy, G. Lange, N. Hirschman, and H. J. Marsh were elected to the Membership of the College.

The Honorary Fellowship of the College was conferred on Professor Bordet of the Institut Pasteur, Brussels, on account of his services to medical science; and the Honorary Fellowship was conferred upon Sir Temulji Bombay, in recognition of his services to medical education in India.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

WILLIAM JOSEPH DEIGHAN, L.R.C.P. and S.I., having passed the examination, has been duly admitted a Member of the College.

The Services.

NAVAL MEDICAL MEMORIALS.

A bronze tablet erected at the Royal Naval Hospital, Chatham, commemorates the medical officers and members of the nursing staff of the hospital who lost their lives during the war was unveiled by Sir Robert Hill, Medical Director-General, on November 11th. The memorial tablet was dedicated by the Rev. H. Lloyd, R.N., a wreath was placed at its base by Surgeon Rear-Admiral G. A. Draper, C.B.

AUXILIARY R.A.M.C. FUNDS.

At the recent quarterly committee meeting of the Auxiliary Royal Army Medical Corps Funds, grants were made to cases in the Benevolent Branch for the orphans of officers, amounting to £11 5s. 11d., and grants in the Relief Branch for the widows and children of the rank and file, amounting to £1301. These funds are for the relief of widows and orphans of commissioned officers, non-commissioned officers, and men of the rank and file of the Royal Army Medical Corps, Special Reserve, Territorial Force and New Armies, and also for the relief of the children of those who have been so severely disabled in the late war that they need help for the education of children. Requests for relief should be addressed to the Honorary Secretary, at the Offices of the Funds, 11, Chandos Street, Cavendish Square, W.1.

Obituary.

J. M. RATTRAY, M.D.,

Date of Frome.

DR. J. M. RATTRAY, of Frome, who was very well known to members of the British Medical Association ten or fifteen years ago, owing to the frequency of his attendance at the Annual Meetings, died suddenly in London on November 4th.

John Moysey Rattray was the son of Dr. John Rattray of Aberdeen, and was born in that city in 1857. He graduated M.A. Aberdeen in 1877, M.B., C.M. in 1882, and M.D. in 1891. After holding the appointment of house-physician to Aberdeen Royal Infirmary he settled in Frome, where he enjoyed a large practice and took an active share in the life of the town. He was for many years police surgeon and medical officer of the union, and at the time of his retirement was senior honorary medical officer to the Frome Victoria Hospital. He was also connected with the St. John Ambulance Association, for which he was a lecturer. He became a member of the British Medical Association in 1883; he was a member of the Bath and Bristol Branch Council for two periods and president of the Branch in 1911. In 1910 he was chairman of the Trowbridge Division of the Association. Dr. Rattray's health had never been robust, and in May, 1917, he was shot at and rather seriously injured by a patient who was in a state of great mental excitement. A long illness ensued, and eventually Dr. Rattray retired from practice and settled in London. He took a great interest in historical subjects, especially those connected with Scotland, and frequently wrote upon them, for he had a facile pen. He was a Fellow of the Royal Historical Society.

He was a man very much esteemed by all who knew him. His honesty of purpose was transparent, and his kindness of heart was constantly finding expression. The funeral, which took place at Frome on November 9th, brought together a very large attendance of friends, and during the day the flags on the public offices and the Conservative Club were flown half-mast.

T. W. PARRY, M.R.C.S. Eng., L.R.C.P. Edin.,

Ferndale, Glamorgan.

THE death took place on November 3rd at Ferndale, Glamorgan, from bronchopneumonia of Dr. Thomas William Parry, J.P. He was born at Dolgelly, North Wales, in 1848, and was educated at Edinburgh, where he was considered one of the best students of his year; he took the diplomas of L.R.C.P. Edin., M.R.C.S. Eng., and L.S.A. in 1871. Some fifty years ago he settled at Ferndale, then a small place of about 1,000 inhabitants, where collieries were being sunk; the population has now increased to 25,000. Dr. Parry became surgeon to the collieries and identified himself with every social and philanthropic movement for the welfare of his district. He was greatly beloved by his patients, and his skill as a surgeon was recognized beyond his own area. He retired from active practice twelve years ago, when he was presented with a valuable testimonial by the townspeople. He was one of the senior magistrates of Glamorgan, and until recently sat regularly at Porth police court, where his portrait was unveiled a short time ago. Dr. Parry was an old member of the British Medical Association and was seldom absent from the Annual Meeting. He was a member of the Council of the South Wales and Monmouthshire Branch from 1888 to 1892, and was Vice-Chairman in 1905 and Chairman in 1906 of the North Glamorgan and Brecknock Division. In 1877 he was one of the twelve medical practitioners who were awarded the Medal for Distinguished Merit of the British Medical Association for heroic conduct and self-denial at

a colliery disaster at Pontypridd. Dr. Parry's wife and two of his daughters died some years ago; he is survived by his two younger daughters.

S. II. writes: As an old assistant of Dr. Parry, I desire to pay a tribute to his many estimable qualities. He was a fine representative of the old school of doctors, possessing a remarkable personality. He was a skilful surgeon, and, working without even the advantage of a cottage hospital, he performed many skilful operations in the homes of his patients. He was a charming colleague, and his invariably good humour relieved the sense of tedium associated with medical practice in the grey surroundings of a colliery district. He was always most sympathetic, and his outlook on life was optimistic. As Horace says (*Odes*, II, 3):

"Omnes eodem cogimur; omium
Versatur urna, scrius, ocias,
Sors exitura."

Medical News.

DR. J. J. E. BIGGS, O.B.E., has been re-elected Lord Mayor of Cardiff. Seven members of the medical profession have been elected to the office of Mayor: Dr. E. A. Farr, Andover (re-elected); Dr. C. F. Oldacres, Daventry; Dr. J. T. T. Ramsay, J.P., Blackburn; Dr. F. L. Thomas, Barstaple; Dr. H. Tibbits, Warwick (re-elected); Dr. H. S. Walker, Louth (re-elected); Dr. J. W. Cleveland, St. Albans. The Lord Mayor of Cardiff and all the medical mayors with one exception are members of the British Medical Association.

THE annual old students' dinner of St. Thomas's Hospital was held on November 10th, at Princes Restaurant, Piccadilly, with Sir Charles Scott Sherrington, President of the Royal Society, in the chair. The company, which numbered over 200, included Sir Anthony Bowlby, President of the Royal College of Surgeons, Sir Robert Hill, Medical Director-General, R.N., Sir George Makins, Sir George Newman, Sir R. Havelock Charles, Sir Seymour Sharkey, Sir F. Stanley Howett, Sir Arthur Newsholme, Sir Walter Fletcher, Sir Archibald Reid, and Sir William Thorburn. The chairman, in proposing the toast of "St. Thomas's Hospital and Medical School," referred to his own days as a student at the medical school, and spoke of its present prosperity. Sir Cuthbert Wallace, dean of the medical school, who replied, reviewed the year's doings, sporting as well as academic. He regretted the absence of the treasurer, Sir Arthur Stanley, on account of the general election campaign, but he could state that the finances of the hospital were healthy and were now within measurable distance of balancing, the deficit being only about £3,000. The scheme for the erection of a war memorial was now well in hand. The health of the chairman was proposed with a wealth of eucoumism by Sir Charles Ballance, and was received with acclamation, and Sir Charles Sherrington briefly responded.

A CHANCEL screen erected in the chapel of the Horton Mental Hospital, Epsom, in memory of the fallen members of the hospital and those who died on service at the institution when it was a war hospital, was unveiled on November 11th. On each side of the screen is a memorial tablet bearing the names of fifteen members of the mental staff, and eleven names of the war staff, including a sister, a nurse, and four captains of the R.A.M.C.

A POST-GRADUATE course on recent progress in surgery and orthopaedics, urology, and obstetrics and gynaecology, with special reference to treatment, to be given by members of the medical faculty of Vienna, will begin on December 4th and terminate on December 16th. The hours from 8 to 11 and 3 to 6 will be occupied on each day. The first lecture will be given by Professor A. Eiselsberg, on the lessons of war surgery for civilian surgery. Particulars as to this course can be obtained from Dr. A. Krenfeld, Porzellangasse 22, Wien IX. Another course of the same kind will be held next year from February 12th to 24th. Courses of instruction in special subjects can also be obtained in Vienna during December.

At the meeting of the Medico Legal Society to be held at 11, Chaudes Street, W.1, on Tuesday, November 21st, at 8.30 p.m., Earl Russell will read a paper on the ethics of suicide.

DR. PORTER PHILLIPS will read a paper on "The position of insanity in criminal law" before the Hunterian Society, on Monday, November 20th, at 9 p.m., at the Cutlers' Hall, Warwick Lane, Newgate Street. Members of the medical profession and of the Medico-Legal Society are invited. A discussion will follow the paper.

DR. HARVEY HILLIARD, formerly Chairman of the Westminster Division of the British Medical Association, is among the recipients of honours bestowed by His Majesty on the advice of the ex-Prime Minister; he is created a Companion of the Order of the British Empire in recognition of public services.

A PAPER on "The economy of smoke abatement" will be read before the Royal Society of Arts, John Street, Adelphi, W.C.2, on Wednesday, November 22nd, at 8 p.m., by Ex-Bailie William B. Smith of Glasgow, a member of the Departmental Committee on Smoke Abatement. Lord Newton will preside.

THE annual dinner of the Chelsea Clinical Society will be held on Wednesday, November 22nd, at 7.30 o'clock, at the Café Royal, Regent Street, W.1.

A MEMORIAL fund has been opened to the late Sir Charles Ryall, C.B.E., F.R.C.S., by the Cancer Hospital, Fulham Road, London, at Coutts Bank. It is proposed that, subject to the necessary funds being forthcoming, the memorial shall take the form of a new operating theatre unit.

THE Department of Scientific and Industrial Research has issued a report of its Food Investigation Board (H.M. Stationery Office, 1s. 6d. net) on the transmission of heat by radiation and convection. It relates a large number of experiments made by Mr. Ezer Griffiths, D.Sc., and Mr. A. H. Davis, M.Sc., directed especially to problems of insulation connected with cold storage construction. Ultimately the inquiry extended beyond this, and yielded results which will be of considerable interest to physicists.

THE Chelsea Clinic of Auto-suggestion, 268, King's Road, S.W., was opened in October, 1921, and is in charge of Dr. Monier-Williams and Dr. Charles Harford, who are testing the treatment of disease of organic as well as of functional origin by the method of collective auto-suggestion initiated by M. Emile Coué of Nancy and expanded by Professor Baudouin of the Geneva School of Psychology. The clinic being entirely free is intended for patients unable to afford ordinary professional fees. Medical practitioners are invited to send any cases they consider suitable. Women are seen on Wednesdays at 5.15 and men on Fridays at the same hour.

A PUBLIC lecture on the pasteurization of the public milk supply will be delivered at University College, London, by Dr. Henry Kenwood, C.M.G., Edwin Chadwick Professor of Hygiene and Public Health, on Thursday, November 23rd, at 5 p.m. The chair will be taken by Sir William Collins.

THE Hunyadi Janos bitter water can now again be obtained in this country. The water is very well known, and the proportion of salts in it is clearly very constant, since the analysis made by Liebig agrees very nearly with others made in recent years. The principal salts are magnesium and sodium sulphates; both are present in the proportion of about 16 parts in the 1,000. The water is bottled at the springs, which rise a few miles south of Budapest, and great care is taken to ensure that the water exported is uniform and free from accidental contamination. The English agents are Messrs. Ingram and Royle, 45, Belvedere Road, London, S.E.1.

DR. R. A. DART has been appointed Professor of Anatomy in the University of Witwatersrand, Johannesburg. He is an Australian by birth, and first attended the University of Queensland, where he took the degree of M.Sc. Afterwards he studied medicine at Sydney University, and graduated M.B., M.S. He served with the Australian Expeditionary Forces, and when demobilized became senior demonstrator of anatomy and lecturer on histology in University College, London, under Professor Elliot Smith.

MESSRS. J. AND A. CHURCHILL announce for early publication: *Sterility in Women, Its Causes and Treatment*, by Dr. R. A. Gibbons; *Applied Pharmacology*, by Dr. A. J. Clark, Professor of Pharmacology, University College; *The Theory of Emulsions and Emulsification*, by Dr. W. Clayton; the second edition of Dr. J. D. Gimlette's *Malay Poisons and Charm Cures*, with a preface by Sir William Wilcoxon; and the eighth edition of *Tomes's Dental Anatomy*, edited by Dr. Mallet Tims and Mr. C. Bowdler Henry.

THE number of street accidents recorded by the Metropolitan Police during the months of July, August, and September reached the total of 15,419. Of these 198 were fatal, 174 being caused by mechanically propelled vehicles.

UP to the time of going to press the following members of the medical profession have been elected to represent the constituencies indicated in the new Parliament which will meet next week: Sir George Berry (Con.), Scottish Universities; Sir John Collie (Nat. Lib.), Glasgow, Partick; Major L. G. S. Molloy (Con.), Blackpool; Dr. A. Salter (Lab.), Bermondsey, West; Dr. T. Watts (Con.), Willington; Sir Wm. Whitla (U.), Queen's University, Belfast. Ten other medical men in the results so far declared have been unsuccessful.

Letters, Notes, and Answers.

wing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Monday and lastest communications on Monday.

1. LETTERS forwarded for publication are to the BRITISH MEDICAL JOURNAL alone.

RESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

Persons desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, Strand, W.C.2, on receipt of proof.

Order to avoid delay. It is particularly requested that ALL letters on editorial business of the JOURNAL be addressed to the Editor at the office of the JOURNAL.

postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic address is:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology, Westrand, London*; telephone, 2630, Gerrard.

2. FINANCIAL, SECRETARY AND BUSINESS MANAGER (advertisements, etc.), *Articulate, Westrand, London*; telephone, 320, Gerrard.

3. MEDICAL SECRETARY, *Mediterra, Westrand, London*; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Acillius, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

QUERIES AND ANSWERS.

PSYCHICAL TRAINING.

MEDICAL practitioner, "P. J." writes: Lord Dawson, during course of his address published in your issue of October 28th, talks of the psychical training of children by the aid of rhythmic, axation exercises, etc. I should be grateful if I could be informed where I could obtain further information on this matter in both practice and literature.

LEFT-HANDEDNESS AND STAMMERING.

C. L. LAPPER (Loughborough) asks for advice in regard to boy, aged 6 years, who is left-handed from birth. "Ought he to be taught to write with his right hand? Also, is there any connexion" between his left-handedness and stammering? He has an uncle who is left-handed and has a pronounced stammer. I cannot trace any further family history of left-handedness or stammering."

WARMING THE GARAGE.

VER" writes: May I ask for the experience of motor users as regards the heating of the garage, thus avoiding the necessity of emptying the radiator every night during the winter, or not refer to the usual steam-heater radiators, but rather to type of stoves advertised in the motor papers.

CLIMATE FOR ARTERIO-SCLEROSIS.

B." a doctor, age 65, suffers from high blood pressure and cannot afford to retire. Where—in England—his life is the best place for him to live? and form of night employment could he do?

A STRANGE "WILD-FOWL."

FRANK G. LAYTON (Walsall) writes: The other day a middle-aged man came into my consulting room very bashfully. Plainly he had something on her mind. She told me she had come on a very funny errand, and she did not like to talk about it. However, I managed at last to persuade her to let me have a look; and as I discovered that whatever it was she had on her mind, there was something entirely tangible on her body. On the front of her abdomen was what looked like a small pedunculated mole, felt disappointed. It seemed a poor thing to be so bashful about. But when I turned it up with a pair of forceps, and looked at it with a lens, I found four moving legs on each side of it at brown body, and a black shiny neck. The snout was in the middle of its skin. I tried peaceful persuasion, with no luck. The patient refused to let go. Then I chloroformed him. Still he sat tight. Finally I dug his head out with a small pair of scissors, and, unhappily, the beast died and dried up; but the patient came cheerful. It appeared that she had been spending a holiday in Surrey, and that three or four days before her visit she noticed something pricking; but she had seen nothing till the day of our interview. Will one of your Surrey readers be kind enough to tell me what it was? For all I know that kind of beast is common in the wilds of the South; I can find no one in the civilized Midlands who has heard anything of its sort.

INCOME TAX.

ON." is about to buy a one-third share in a practice in which has been acting as assistant for the past year. Abnormalization of book debts has swollen the cash receipts so that the correspondent anticipates that he will in the future have to share his share of an average assessment inflated beyond the then probable yield of the practice.

* Under Rule 11, Cases I and II, Schedule D, "where a change occurs in a partnership of persons engaged in any . . . profes-

sion . . . the tax payable in respect of the partnership . . . shall be computed according to the profits . . . during the periods . . . prescribed"—that is, during the three years' average—"unless the partners . . . prove to the satisfaction of the Commissioners that the profits have fallen short . . . from some specific cause since such change took place . . . or by reason thereof." We suggest that "Oxon," ask the Inspector of taxes whether he agrees that this provision will enable the firm to claim a reduction of the 1923-24 assessment to the profits of the year if they should fall below the amount of the assessment as determined by the past average profits. It appears to us that this claim would be in order, and that it provides an avenue of escape from the hardship which "Oxon," would otherwise suffer.

"K. A. C." is in the employment of a county council and receives an allowance of £250 a year for the use of a car in his work. He calculates that this approximately equals the annual running cost and has claimed the cost of replacing his car as a deduction from his salary.

* We do not know the precise terms of the council's grant of £250 a year, but in general such allowances are intended to cover all necessary car expenses, including periodical renewal. "K. A. C." is entitled to be assessed on the salary plus allowance after deducting all "expenses incurred wholly exclusively and necessarily in the performance" of his duties, but we apprehend that he will find great difficulty in convincing the income tax authorities that the specific council allowance of £250 is insufficient to cover those expenses. He has, of course, a right of appeal to the General Commissioners for Income Tax of his district.

LETTERS, NOTES, ETC

HYPERTROPHY OF THE PROSTATE.

DR. J. HENRY writes: The common enlargement of old age is due chiefly to increase of the muscular substance. It occurs in about 30 per cent. of men over 60 (Coates's *Manual of Pathology*, 1893). Is fibroid prostate a disease or is it like the muscular arm of the blacksmith? The ergography of the prostate has not been estimated, still less the functional activity of its muscles. The disease of muscle does not lead to hypertrophy.

NORTHUMBERLAND YEOMANRY.

AN advertisement is published this week asking for information as to Trooper J. L. Pumphrey, Northumberland Yeomanry, who was severely wounded in Polygon Wood on October 24th, 1914. He is supposed to have been sent by the 4th Field Ambulance to the convent school of St. Charles, between Potijze and Verlorenhoek, near Ypres.

THE VIOLATORS OF VACCINATION LAW.

DR. H. P. REYNOLDS, F.R.C.S.E., Public Vaccinator (Upwell, Wisbech), writes: "The persons responsible for the thousands of unvaccinated people in Britain are the ignorant people called justices of the peace. A mother gets a vaccination paper for her child and at once rushes off to a J.P. with some cock-and-bull story, and scenes without difficulty an order absolving the child from the operation. Every month I come across mothers who pride themselves on their cleverness; I tell them the time will come when they will regret their silly action."

MOTOR CAR SHOW IN LONDON: A CORRECTION.

THE price of the 23-50-h.p. Vauxhall-Kington open touring car, referred to in the article on the Motor Car Show in London (November 4th, p. 879), is £895, and not £1,150 as printed.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 33, 39, and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 191.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postage letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

372. Sthenic Dyspepsia, or Hyperchlorhydria.

J. J. GRAHAM BROWN (*Edinburgh Med. Journ.*, October, 1922) approves Rosenbach's dictum that the great majority of cases of gastric disorder are originally of nervous origin, whatever complications may ensue. He emphasizes the necessity of studying the physiology of gastric activity and of the experimental findings of the laboratory. The mere study of symptoms in human patients must remain almost futile without the sure foundation of physiology. He then describes the twofold innervation of the stomach—sympathetic and parasympathetic—the one leading to atonic and the other to hypertonic conditions; if one be depressed by toxic or other causes the other autonomic system becomes dominant. Conversely, one may be hyperstimulated and so overpower the other. The efferent parasympathetic neurones of the vagus which control the activities of the stomach are mainly (1) motor and (2) secretory; both may be disturbed separately, but more usually both are involved to a greater or lesser degree. Motility varies in different parts, the fundus acting chiefly as a food receptacle (Caumon), but is not entirely quiescent. Terminal fibres of both vagi form synapses with Auerbach's plexus, and efferent stimuli start peristalsis in the prepyloric region, and may be stimulated by pilocarpine and inhibited by adrenalin; Mann and others claim that adrenergic insufficiency is found in many cases of acute gastric ulcer. Pure gastric juice is of fairly constant acidity—0.5 per cent. HCl; but this is reduced by saliva, mucus, and by reflux of duodenal secretion to 0.2 per cent. The term "hyperchlorhydria" is therefore not accurate—it often denotes excess of "appetite-juice" from vagal hyperactivity. The physiological importance of free HCl is described, and the inhibition of gastric secretion by emotional stimulation of the sympathetic. Hypersecretion is due to (1) absolute or (2) relative vagal hypotonus. Inhibition of secretion is due to vagal hypotonus—(1) absolute (from toxic poisoning as in enteric, or from the action of drugs such as atropine, or from exhaustion) or (2) relative (emotion producing endocrine stimulation). Although the nerve mechanism regulating secretion may be intact, pathological changes in the mucous membrane (for example, cancer or chronic alcoholism) or unsuitable food may produce achylia. Overstimulation of the parasympathetic, stated to be more common in men, results in increased peristalsis and increased secretion of gastric juice; the patient is active and vigorous and complains of pain, relieved by food, or the pain may come on shortly after taking food, owing to increased peristalsis—the lighter the meal the more rapidly does the stomach empty itself. The highly acid stomach contents may cause painful pyloric spasm, and when the stomach is empty pain returns, there is heartburn, flatulence, acid eructations, and sialorrhoea. The patient eats rapidly and masticates insufficiently. A bismuth meal and skiagrams show hypertonus, the greater curvature above the umbilicus, active powerful peristalsis, and possibly bismuth-containing "pockets" in the stomach or duodenum, indicating an ulcer. A test meal will show excess of acid, and the percentage of free plus organically combined HCl should be estimated. This may rise to 0.3 or 0.35 per cent. Flatulence results from neutralization of large quantities of alkaline saliva with liberation of free CO₂. In these cases the pupils are small (sympathetic hypotonus), the oculo-cardiac reflex may be so marked that the radial pulse may disappear, and the "exercise tolerance" test is very good. When untreated these cases suffer from exhaustion of the gastric muscular wall eventually, and secondary gastroparesis with the usual symptoms follows. The stomach now never completely empties itself except by vomiting. Treatment, in the first stage, is directed to vagus depression—that is, to control peristalsis and lessen HCl secretion. In the later stage of dilatation the object is to restore motor activity and to prevent toxæmia. Stimulation of the sympathetic by mental and physical exercises is recommended. Moderate fatigue will stimulate the adrenals, and small doses of thyroid extract act as stimuli to the sympathetic system. Tincture of belladonna, alkalis, and a salt-free diet tend to lessen secretion of HCl. Prolonged mastication of food increases the secretion of saliva, and consequently the alkalinity of the mass when swallowed. Stimulants and condiments are to be avoided, and the dietary should include plenty of soluble fat. Green vegetables and stale bread are recommended, and potatoes, carefully steamed, may be eaten in small quantity.

373. X-Ray Treatment in Skin Diseases.

GUARINI (*Rif. Med.*, September 11th, 1922, p. 876) describes some of the established results in the x-ray treatment of skin diseases. For most cases it is better to use hard rays well filtered. Primary cancer of the skin usually responds excellently, and secondary nodules—for example, after the removal of the breast for cancer—are often much improved. Even where the case appears hopeless the mental effect of x-rays may perhaps be worth trying. Port-wine stains are better treated by radium or electrotherapy; cavernous naevi do well with x-rays. Keloid, warts, condylomata, and mycosis fungoides are also favourably influenced. The technique for x-ray treatment of ringworm is now well known and accepted as the most efficacious form of treatment. In treating the face it should be remembered that this part of the body is specially sensitive to x-rays. The results in hypertrichosis are often very good but variable. For ordinary desfluvium capillorum and alopecia x-rays are often used. Acne, furunculosis, hyperidrosis, rhinoscleroma, psoriasis (in this case applying the rays to the thymus), pruritus (except the neurosis type), and seborrhoea are also mentioned as favourable cases for this treatment.

374. M. V. LEOF (*New York Med. Journ. and Med. Record*, October 4th, 1922, p. 379) discusses the value of x-rays in the treatment of skin diseases. The effectiveness of the treatment is due to the fact that x-rays produce chemical action by oxidation, and that, by their biochemical action, they modify the production and action of enzymes and ferments, besides possessing bactericidal powers. While a minute amount of radiation stimulates, large amounts inhibit and destroy, and undifferentiated, immature, biologically or physiologically active cells are most readily affected. In the treatment of acne vulgaris x-rays are superior to any other methods, ten to sixteen fractional doses usually effecting a cure, and in the treatment of furunculosis, tinea tonsurans and barbae, and in favus it gives the best results. In syphilis vulgaris the effects of x-ray treatment are not constant, and its application should be in conjunction with other methods, such as vaccines, etc. Nearly all forms of eczema derive benefit from the treatment, though it should not be applied in acute or inflamed conditions. While in psoriasis a ready response is obtained recurrences are common, and it is of doubtful value in general pruritus, though distinctly useful in regional pruritus. Except in the ulcerative type of lupus the treatment is of little value, as is the case in tuberculosis of the skin and allied conditions, though in tuberculous adenitis a large percentage of cases are cured. Warts, senile keratosis, benign new growths, and rhinoscleroma respond well to x-ray treatment, but with the exception of the cavernous type it is unsatisfactory in dealing with naevi. In basal-cell epithelioma x-rays are the only known prophylactic, and should be resorted to early, but the results are not so favourable in prickle-cell epithelioma because of the likelihood of metastases taking place.

375. The Dangers of Phenolphthalein as a Purgative.

K. SCHMILINSKY (*Deut. med. Woch.*, September 29th, 1922, p. 1311) considers phenolphthalein a dangerous drug which is capable of causing wholesale destruction of the red blood corpuscles, and inducing acute toxic degeneration of the kidneys. The author, who gives references to previous cases, records the case of a girl, aged 9 years, whose mother gave her, in one dose, two tablets, each of which contained 0.1 gram of phenolphthalein. A normal evacuation followed, but next day there was violent pain in the right abdomen, with fever, nausea, and vomiting. The rectal temperature was 39.3°, the pulse 130 to 145. The region about McBurney's point was very tender and hard, and, perityphilitis being suspected, laparotomy was performed. But the only abnormality found was a number of threadworms in the appendix, which was macroscopically normal. Next day the condition of the temperature and pulse was unaltered, the ribs and sternum were tender on percussion, and a blood count showed 3.5 million erythrocytes, 73 per cent. haemoglobin, 57,000 leucocytes, 90 per cent. of which were neutrophils, 9 per cent. monocytes, and 1 per cent. lymphocytes. By the eleventh day the number of the erythrocytes had risen to 4.5 million, and the leucocytes had fallen to 12,700. A few days later the number of leucocytes was further reduced to 6,700. The author, who interprets these phenomena as signs of irritation of the myeloid system by phenolphthalein, advises caution in its administration.

376. Pathological Dentition.

V. MACDONALD (*Med. Journ. of Australia*, September 9th, 1922, p. 290) considers pathological dentition to be a definite clinical entity, and that though dentition is normally physiological it may become pathological. In the eruption of teeth the action of the ductless glands, such as the pituitary and thyroid, has to be considered, there being a direct relationship between the growth of bone and their eruption and growth. The stages of eruption and the relation of the teeth of the first dentition to those of the second point to a period of great physiological activity not without pathological possibilities in a delicate organism of developing cells in various stages of completion and specialization, in finely adjusted balance easily upset by a storm centre in any portion of the organism, and dependent for its stability upon the nutritional and physiological balance of the entire organism. Anything which upsets this balance will impair harmony between the root growth and the absorption of the tissues overlying the tooth crown resulting in a steady backward pressure of the calcified portion of the tooth root upon the dentinal papilla, and so setting up any, or all, of the phenomena of pathological dentition. The tooth thus becomes a mechanical irritant, and thorough lauding of the teeth next in order of eruption in cases due to dentitional upset is said by the author to give excellent results. Of the second dentition the chief abnormal nervous phenomena are mainly due to impacted or misplaced teeth, but even when erupting in correct alignment they may be subjected to backward pressure, the second and third molars being the most frequent sources of trouble in this respect. Without attributing too much to dentitional disturbance, or confusing coincident disease with that incident to dentition, the possibility of a perfectly normal physiological process occasionally becoming pathological and a factor in the causation of disease is maintained.

377. Herpetiform Eruptions in Encephalitis Lethargica.

ARNOLD NETTER (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, July 6th, 1922, p. 1028) states that he has seen herpetiform eruptions in the course of encephalitis lethargica in two cases and has found records of three others; he considers that they occur in at least 1 per cent. of all cases. Guizotti (Parma) and Bérlet (Lyon) have described the pathological changes found in the posterior spinal root ganglia and in their cranial homologues in the case of two women who died after twenty and twenty-six days' illness, which commenced with intense pain accompanied by myoclonic spasms. The ganglia and nerve roots showed an inflammatory exudation, consisting chiefly of lymphocytes with a few plasma cells. The nerve cells were largely retracted and the nuclei were opaque and atrophic. These changes were found in all the nuclei of the sensory nerves of the areas in which latent pain had occurred during life. Netter's first case was that of a healthy man of 34 in whom intercostal herpes preceded (by nine days) an attack of myoclonic encephalitis, from which he recovered. The second case was a child in whom intercostal herpes and encephalitis occurred simultaneously; she recovered. In the third case, reported by Medea (Milan), the encephalitis was accompanied by supraorbital herpes, followed by paraesthesia of the affected area. In the fourth case (Souques) bilateral herpes zoster followed the encephalitis eight months after its onset; myoclonic spasms of the left side persisted. In the fifth case (Simono) the patient was aged 8½ years. Encephalitis commenced on March 25th. On April 6th bilateral genital herpes appeared. Patient was admitted to hospital on May 27th quite unconscious. The child died on October 10th of streptococcal meningitis. Histological examination of the brain and salivary glands showed changes characteristic of encephalitis. On April 21st (that is, fifteen days after this patient developed herpes) another child in the same ward (admitted February 2nd) developed varicella, and on May 5th another little girl (admitted March 13th) also developed confluent varicella.

378. Treatment of Whooping-cough with Ether.

MANCINELLI (*La Pediatria*, September 1st, 1922, p. 801) gives the results of the ether treatment of whooping-cough in 36 children treated as out-patients and 35 as in-patients. For children of 1 year 1 c.c.m. of ether prepared according to a formula of Professor Valagussa was injected on alternate days, the dose being increased with the age of the patient. In the out-patient group the results were remarkably good, but in the in-patients less than half gave any good result, but in most of these cases there were complications—for example, severe rickets. The five deaths in the second group were due to bronchopneumonia. No bad effects were observed after the injections. Apart from the complications present the better results obtained in the first group were probably due to the greater freedom to air.

SURGERY.

379. Acute Staphylococcal Osteomyelitis of Femur Cured by Vaccine Treatment.

EGIDE CLAES (*Le Scalpel*, September 23rd, 1922, p. 919) records the case of a rachitic child, aged 2½ years, who while playing fell on her left leg. She felt no pain at the time, but in the night complained of pain in the thigh and knee, could not sleep, and kept the knee and hip flexed, with thigh everted. Three days after the fall the lower part of the left thigh was swollen and very tender; the child refused food, and sweated profusely; the temperature was 38.5° to 40° C. Applications of liq. plumbi subacetic. dil. relieved pain and reduced the temperature to 38°. She was admitted to hospital fifteen days after the fall. She was wasted, pale, temperature 38.6°, pulse 128, urine normal. The local symptoms—acute tenderness, slight subcutaneous venous dilatation, inability to move the limb, knee flexed at 90 degrees, with brawny swelling of the lower part of thigh and thickening of femur in epiphyseal region—suggested the diagnosis of osteomyelitis; this was confirmed by absence of pus on exploratory puncture and a skilgram showing no bony lesion. Vaccine treatment was ordered, the vaccine being that of the Pasteur Institute containing *Staphylococcus aureus* three parts, *Staphylococcus albus* one part. The first dose injected hypodermically into the right thigh was 500 million; temperature fell from 38.6° to 37.5°. Next day 1,000 million were given; temperature fluctuating, but swelling less and general condition better. On the third day the dose was 2,000 million; temperature fell to 37.2° at night; local and general improvement. On the fourth day the dose of 2,000 million was repeated; temperature fell to 37°, and did not rise at night. On the fifth day no injection; marked general improvement. Next day 4,000 million were given. No injection on the seventh day, but the same dose was repeated the next day, when fluctuation appeared on the inner side of the thigh; 20 c.c.m. of thick yellow pus mixed with blood was evacuated. Examination showed much phagocytosis of staphylococci by polymorphs, very few free cocci. These intervals followed by increasing doses were observed; on the tenth day after 6,000 million had been given; the temperature varied from 37.3° to 37.7°; 10 c.c.m. of pus, as on the seventh day, were evacuated. On the twelfth day a 7,000 million dose was given; temperature did not fall below 37°; slight cough with rales at left base. Next day temperature fell to normal. The injections caused no local reaction and only slight rise of temperature. After an interval of ten days, in order to prevent a relapse, five more doses, varying from 1,000 to 8,000 million, were given from the twenty-third to the twenty-eighth day after admission to hospital. In the first twelve days the child received doses amounting to 25,500 million, and in the second series of injections 23,000 million—equal to a total of 49,500 million. Claes observes that the usual intervals between injections were observed, but he believes the rapid improvement was due to the very large doses employed—"in any case one may conclude that even after these large doses of vaccine the reaction is slight, apparently even insignificant."

380. Intracranial Haemorrhage in the Newborn.

D. MUNRO and R. S. EUSTIS (*Amer. Journ. Dis. Children*, October, 1922, p. 273) suggest an etiological classification of intracranial haemorrhage in the newborn, and report methods of diagnosis and treatment which proved successful in 14 cases. The classification indicates: (1) a traumatic group in which the haemorrhage is caused by excessive moulding of the head and overriding of the sutures; (2) an asphyxia group resulting from excessive cerebral venous congestion with rise of intracranial pressure; (3) a foetal disease group in which the haemorrhage has no relation to the labour, but is most commonly caused by haemorrhagic disease, and rarely by syphilis and other toxæmias. Diagnosis rests upon the history and physical examination, the measurement of intracranial pressure by spinal manometer, and the determination of the coagulation and bleeding time; the result of these findings enables a proper classification to be made so that suitable treatment can be adopted. The normal bleeding time in the newborn is from two to five minutes, and can be estimated by noting the length of time a wound of given depth will bleed, while the normal coagulation time, estimated by observing how long it takes a drop of blood to clot sufficiently to arrest the movement of a small lead shot within it, is from five to nine minutes. Cases showing a prolonged bleeding and coagulation time should be classed and treated as haemorrhagic disease irrespective of other findings. Diagnosis in traumatic cases rests upon the history and, in most cases, evidence of trauma, while in asphyxia cases it rests upon manometric findings of increased intracranial pressure, microscopic blood in the cerebro-spinal

fluid, together with a history of dry or prolonged labour, deep anaesthesia, or prematurity. All cases, whatever their cause, suffer from complicating acute hydrocephalus, and symptoms become worse or fatal only because of the increase in intracranial pressure, and attempts to relieve the hypertension may prevent death, although the haemorrhagic renalitis untreated, since it is only in very favourable cases that surgical removal of the clot is possible. In cases due to haemorrhagic disease treatment consists in the subcutaneous administration of normal whole blood until the bleeding and coagulation times become normal, to be followed by relief for the hypertension. In traumatic cases treatment aims at the prompt elevation of depressed fractures and, as also in asphyxia cases, relief of hypertension by lumbar or ventricular drainage, puncture, or typical subtemporal decompression.

381. Blood Nitrogen in Surgical Lesions of the Kidney.

W. H. OLIMSTED and J. R. CAULK (*Journ. Amer. Med. Assoc.*, October 21st, 1922, p. 1380) point out that there is considerable difference in the interpretation of the retention of blood nitrogen in the different classes of kidney disease. In chronic nephritis, as seen in the medical wards of any hospital, there has been a gradual destruction of kidney tissue, analogous, from the functional standpoint, to the experimental surgical removal of kidney tissue. In the infectious and obstructive processes of the genito urinary tract seen by urologists, on the other hand, the loss of kidney function, after drainage and removal of the obstructions, may be partially regained. If the latter conditions have gone on long enough, permanent loss of kidney function results, just as in the case of chronic nephritis. In the authors' experience, the cases of chronic nephritis were not materially improved, as shown by the failure of the non-protein nitrogen to go down after having reached this level, and by the high death rate. In cardiac patients, unlike those suffering from nephritis, recovery from retention of nitrogen depends entirely on how well the heart will respond to treatment. In the authors' opinion, if the blood nitrogen does not reach a normal level within a month of hospital treatment it will never do so. The interpretation of the retention of urea depends on the nature of the disease present, and especially on the presence or absence of systemic intoxication. With retention of urea bilateral disease is always present, whether anatomical or functional or both.

382. The Technique of Laryngectomy.

R. BOTEY (*Rev. de laryngol., d'otol. et de rhinol.*, September 30th, 1922) thinks that in spite of the progress made in the treatment of cancer of the larynx by means of radium and x-rays, the results have not been encouraging. The best results follow early and radical operation. In his operation he avoids pharyngeal fistulae by the following technique. Instead of using two purely cutaneous flaps, he includes the sterno-hyoid and omo-hyoid muscles, which reinforce and increase the nutrition of the flap. Non-union of the edges of the wound and a pharyngeal fistula are nearly always due to placing the cutaneous sutures over those of the pharynx. In his operation the flap comprises muscle and skin, is thick and well nourished. The aesthetic result of the single flap with its base at the hyoid is good, the scar following the lines and folds of the neck. Another advantage of this flap is that in cases of infection with sloughing and prolonged suppuration, fistulae and unsightly scars do not follow. This flap is chiefly useful in cases of intrinsic cancer, without glands or invasion of the pharynx. When the case is not simple it is better to employ two flaps, for in these cases one is not certain of being able to close the walls of the pharynx by immediate suture. The purely cutaneous flap is thin, the pharynx being covered by the skin alone. The author finds it preferable that the muscles should cover in the oesophagus and the hypopharynx.

383. Neuropathic Keratitis a Result of Focal Infection.

J. W. CHARLES (*Amer. Journ. Ophthalmol.*, September, 1922, p. 703) considers that dendritic and neuropathic keratitis are caused by lesions of the terminal divisions of the corneal nerves, and a case of neuropathic keratitis is reported which rapidly cleared up after treatment of subacute ethmoiditis on the side of the affected eye. A neurotic girl, aged 22, gave a history of influenza followed after a week by watering and redness of the right eye. On examination six days later small branching corneal ulcer, photophobia, lachrymation, and ciliary injection were present, and remained unrelieved by all the usual local remedies. A badly decayed right lower third molar received dental treatment, without relief to the eye symptoms, and it was not until she received palliative treatment for a mild suppurative subacute ethmoiditis on the right side that the eye began to improve, the ulcer having healed two days later, though the ciliary injection lasted

longer before finally disappearing. In support of the theory that such terminal lesions may result from focal infections may be quoted those neuralgias without any other apparent complication which are relieved by treatment of the offending focus.

OBSTETRICS AND GYNAECOLOGY.

384.

Treatment of Eclampsia.

T. W. EDEN (*British Journ. of Obstet. and Gynaecol.*, Autumn, 1922, p. 386), in a commentary on the reports, dealing with eclampsia, presented to the British Congress of Obstetrics and Gynaecology (June, 1922), states that the mean mortality of 2,065 cases was 22.5 per cent.; the mortality among 204 Dublin cases was 10.29 per cent., and that of other regions from 21 to 25 per cent. In 65 per cent. of the Dublin, and from 44 to 54 per cent. of the other cases, the infant left the hospital alive. Primigravidae numbered 69.3 per cent. of the grouped series. Premonitory symptoms appeared to have preceded eclampsia in about 85 per cent. of cases, but cases in which such symptoms were not noticed did not seem to be more severe than others. Cases in which there was deep coma, a pulse rate of over 120 a minute, a temperature of over 103°, or a blood pressure of over 200 mm., gave a mortality rate considerably in excess of the average, and lethal cases had sustained on an average nearly twice as many convulsions as the others. Reviewing the mortality in connexion with various methods of treatment, the author sees in the figures a very powerful plea for restraint in the obstetric management of cases of eclampsia, and remarks that Caesarean section and forcible dilatation of the cervix diminish instead of increasing the patient's chances of recovery. All cases of eclampsia, whether mild or severe, are best treated with the minimum of obstetric interference. Not only the Dublin mortality figures, but also analysis of the other group reports, appear to indicate that active and early obstetric intervention, as advocated by Dührssen and others, should be discarded in favour of expectant and eliminative therapy along the lines advocated by Stroganoff and by Hastings Tweedy. Eden points out that since it is easier to prevent than to cure eclampsia, prophylaxis is all-important; it should assist in treating patients who have shown albuminuria, oedema, headache, or visual disturbances, accompanied more rarely by epigastric pain, vomiting, muscular twitchings, or attacks of petit mal, by rest in bed, fluid diet only (mostly water), purgatives, and diaphoretics. If progress is unsatisfactory or if relapses occur, labour should be induced without regard to the period of the pregnancy or the chances of foetal survival. Eclampsia having passed beyond the pre-eclamptic stage calls for hospital treatment as urgently as the most serious surgical operation.

385

Prognosis in Sterility.

ACCORDING to H. R. SCHMIDT (*Med. Klinik*, 1922, 23, p. 722), about one-third of cases of sterility in the female are attributable to morbid conditions of the husband; of other cases, about one-third are due to gonorrhoea in the female and about two-thirds to an infantile condition of the female genital organs. In the last-named group prognosis as regards possibility of child-bearing may to a certain extent be guided by the history and objective findings. If there has been menstrual irregularity characterized by long periods of amenorrhoea, and if the uterus is of subnormal size, probably ovaries and tubes are underdeveloped and the outlook is unfavourable. If menstruation is regular and bimanual examination shows a corpus uteri of normal size and well-developed uterine appendages, prognosis is much better, many of the cases being connected with abnormalities of the cervix. In these cases Schmidt recommends Fehling's method of cervical dilatation; for three successive periods of three days a glass tube of the thickness of a pencil, having a plate-like expansion at the outer end, is left within the cervical canal, the cavity uteri being injected with 1 per cent. formalin on several occasions. Not all subjects tolerate this procedure, but at the Lund and Bonn clinics pregnancy is reported to have ensued in about one-third of the cases in which it has been used—some patients, however, have been married for less than four years. A. MAYER (*Zentralbl. f. Gynäk.*, September 23rd, 1922) believes that genital hypoplasia plays a considerable part in causation of sterility; especially among patients seen in private as distinguished from hospital practice. In certain cases uterine retroflexion is responsible, but its correct or, on account of the associated hypoplastic conditions, does not necessarily cure the sterility. He has found cervical dilatation and curetting to be followed by pregnancy in 20 per cent. of cases. The examination of the fragments removed by curetting may be of diagnostic and

prognostic utility; absence of signs of the cyclic endometrial changes may be found, or, as in no fewer than 7.8 per cent. of Mayer's cases, evidence pointing to tuberculosis.

385.

Treatment of Sterility.

ACCORDING TO BETHEL SOLOMONS (*Irish Journ. of Med. Science*, September, 1922, p. 303), treatment by administration of extracts of ductless glands is sometimes strikingly successful in sterile females. Those having scanty menstruation should be given corpus luteum in doses of 5 grains daily for two days, gradually increased to three times this amount; extracts of the whole ovary are less useful but less expensive. When sterility is associated with excessive obesity and oligomenorrhoea or amenorrhoea, thyroid extract may be given in 1/2 grain doses three daily; pituitary, testicular, and pineal-glandular extracts are not recommended. With regard to operative treatment the author remarks that curettage or cauterization of the uterus is very seldom indicated and often harmful, but that occasionally it is right to curette a sterile subject who suffers from severe menorrhagia. Some form of dilatation of the cervix is often necessary. Hegar's dilators may be used up to a size which does not induce laceration, and iodoform gauze two inches wide may subsequently be left for twenty-four hours in the cervix. In this way a permanent dilatation may be secured—for example, of 8 mm. after instrumental stretching to 12 mm. Posterior splitting of the cervix is only indicated in extreme ante-flexion, and if performed with stretching by catgut instead of silk worm gut is apt to be followed by troublesome leucorrhoea. Tubal disease is the most commonly overlooked etiological factor in sterility and may have no other symptom than that condition. Tubes of normal shape, size, and position, save that the abdominal ostia are closed, are treated by Solomon's as follows: If possible the obstruction is removed by expression, and, if not, the amputated extremity is resected, in either case a plug of eight strands of No. 4 catgut being left within the lumen. When the tubes are of normal size and shape, but bound down by adhesions, they should be freed and inflated, and the amputated extremity, if it has been injured during the operation, carefully sutured, strands of catgut being left within the ostium; the prognosis in these cases is excellent. For stenosis of the tube remote from the ostium abdominal a plastic operation is described, a portion of tube being resected and a strand of No. 2 catgut being left, traversing the reconstructed oviduct and penetrating at its respective ends, which are then united to the fundal musculature and the abdominal ostium. In cases of bilateral sacrosalpinx the raw surfaces of tubes left after puncture or resection are sutured, and in the case of hydrosalpinx catgut is threaded through; to meet the risk of local peritonitis and abscess formation Douglas's pouch is opened at the end of the operation and a forceps passed through it per vaginam. The abdomen is opened on to the forceps and iodoform gauze drawn out to the vulva.

387 Uterine Cancer of Unusually Long Duration.

H. L. COOPMAN (*Nederl. Tijdschr. v. Geneesk.*, October 21st, 1922, p. 1844) remarks that Martha and Jung in their textbook on diseases of women have drawn attention to the fact that many women in advanced life with cancer of the uterus apparently die of old age without the uterine condition giving rise to any obvious symptoms. He records the case of a woman who had undergone a supravaginal amputation of the uterus for malignant disease at the age of 47, and consulted him three years later for haemorrhage, when an inoperable cancer was found. The patient survived for another seven years in a fairly comfortable state under palliative treatment only, and then died suddenly. There was no autopsy.

PATHOLOGY.

388. Treatment of Intestinal Tuberculosis.

T. REDMAN (*Journ. of Path. and Bact.*, October, 1922, p. 433), after observing that intestinal tuberculosis is more frequently due to the bovine bacillus in children, whereas in older people secondary intestinal tuberculosis due to the human bacillus may follow swallowing of sputum, proceeds to describe the course and distribution of intestinal tuberculosis in the human subject and in animals, and remarks on the essential similarity of the disease in each species. There then follows an account of experimental work carried out to test the therapeutic value of naphthalene emulsion in the treatment of this disease in guinea-pigs artificially infected by feeding with heavily infected sputum intimately mixed with a bran-mash. Striking results were obtained when such infected animals were treated with naphthalene emulsion, the formula for the preparation of which is given in the paper. Only one dose of the tuberculous material was given to the animals, and then,

after varying periods, a constant dose of naphthalene emulsion was given for a week or ten days to check the course of the disease. The animals were killed at different dates to observe the effects of the naphthalene emulsion, a post-mortem examination being made on each animal. Untreated animals acted as controls. Tuberculous infection of twenty days' standing appeared to be completely eradicated after the use of naphthalene emulsion in some cases, and in others the rate of progress of infection of the lymph glands was markedly retarded. Seventy-five days after the administration of naphthalene emulsion to infected animals the only evidence of tuberculosis was in three small caecal glands, the control animals showing great enlargement of mesenteric and other glands, while in 111 days the mesenteric glands of treated animals were enlarged but no others, and there was no infection of the organs such as occurred in controls. Infection of the spleen, one of the first organs to suffer in the ordinary course, was prevented for between fifty-four and seventy-five days; the liver and lungs were protected from infection for about 115 after ingestion by the animal of tuberculous material. Even in very severe cases of infection life was prolonged. Microscopically it was found that in the tuberculous glands of the treated animals the typical tuberculous structure was replaced by the formation of fibrous tissue much earlier than in untreated animals.

389. The Humoral Reactions of Pleural Fluid.

P. COURMONT (*Journ. de méd. de Lyon*, October 20th, 1922, p. 617) has made a study of the serological reactions of pleural effusions, with especial reference to the question of tuberculosis. He finds that in the case of adults suffering from this disease no fewer than 76 per cent. of fluids agglutinate an emulsion of tubercle bacilli to a titre of at least 1 to 5, while with fluids withdrawn from non-tuberculous individuals there is a failure of such agglutination to occur. A positive reaction therefore affords a strong presumption in favour of the existence of tuberculosis. Apparently the agglutination titre is highest in benign cases of pleurisy, especially during the period of recovery; while in the severer forms and during relapses it may be lowered even to complete disappearance. This point may be used for prognosis. Thus, out of 115 tuberculous individuals, whose histories have been followed over a period of some years, 75 per cent. of those which gave a positive agglutination reaction recovered, while of those which gave a negative reaction 73 per cent. died. Further, the higher the titre given the greater was the percentage of recoveries. He has obtained some evidence, from a comparison of the agglutinin content of the pleural fluid and the blood serum of the same patient, that a local formation of antihodies may occur in the pleura. These antihodies he considers to be of value to the patient, and therefore advises against the withdrawal of fluid except in chronic cases. He also uses this fact to support the practice of autoserotherapy in suitable cases. He appears to consider the agglutinin titre of the fluid as a measure of its antihody content; this has not been the experience of most workers.

390 Artificial Pneumothorax in the Rabbit.

THAT the effects of artificial pneumothorax in the cure of pulmonary tuberculosis are different in the rabbit from those in the human being is shown by J. S. VALTIS (*Ann. de l'Inst. Pasteur*, September, 1922, p. 664). Six rabbits were used for experimentation. Two were kept as controls, and were injected—one intratracheally, the other both intravenously and intratracheally—with living human tubercle bacilli. Killed from eight to eleven weeks later, both were found to have their lungs infected with tubercle in the form of small granules. Two other rabbits were similarly infected with tubercle bacilli, but were subsequently submitted to artificial pneumothorax on the right side, the operation being repeated every few days so as to maintain the pulmonary collapse. Both of these rabbits died on after eight weeks, the other after eleven weeks from the date of inoculation. In each case the right lung was retracted towards the hilum; both lungs contained lesions of caseous pneumonia, those on the right side being the more marked. In two other rabbits artificial pneumothorax was induced and maintained on the right side, and then infection with tubercle bacilli carried out either intravenously or intratracheally ten to twelve days later. The collapse of the lung was kept up till the animals were killed fifty-two to fifty-six days after inoculation. In each case both lungs were affected with tubercle, and in each case the lesions on the right side were greater than those on the left. In all of the four rabbits operated on the infection of the lungs was more advanced than that in the control animals. The author concludes that in the rabbit the effect of artificial pneumothorax is to facilitate the development of tuberculous lesions in the lungs, particularly in the lung of that side on which the operation is performed.

The Doctor's Car

At £630 the 12-24 h.p. De Dion Bouton 3-5 seated Allweather-Coupé is undoubtedly the most remarkable value offered among moderate-powered cars of established reputation and proved reliability.

Its ease of control, ample power, silky suspension and economical running (30-35 miles per gallon) make it pre-eminently suited to medical men's work.

Chassis with 5 tyres ... £415

Complete cars from £525 to £725

12-24 h.p. 3-5 Seated Allweather-Coupé—£630.
(Hood folds down)

INFLUENZA

AND ITS SUCCESSFUL TREATMENT BY

Litmopyrine (BISHOP)

SOLUBLE LITHIUM ACETYL-SALICYLATE

Prompt and Definite in Action. Does not Upset the Stomach.

Antipyretic.—Litmopyrine effects most rapid temperature reductions. The fall begins about fifteen minutes after administration, reaches the minimum within the first hour and lasts for three to four hours, at expiration of which period the dose may be repeated if necessary.

No Harmful By-effects.—Litmopyrine being freely soluble, passes at once through the stomach unchanged, and therefore unlike the insoluble Acetyl-salicylic acid, which splits off its salicylic acid in the stomach. Litmopyrine never causes gastric irritation, nausea or loss of appetite. Litmopyrine has no harmful effect on the heart or kidneys, and does not cause ringing in the ears.

BISHOP'S LITMOPYRINE is free from all the faults and defects of Acetyl-salicylic acid, and is a much more efficient, reliable and successful

antipyretic, analgesic and anti-rheumatic. Its introduction has overcome the last obstacles to the satisfactory administration of the salicylates, and the salt is now widely prescribed for Muscular and Articular Rheumatism, Polyarthritis, Neuritis, Sciatica, Gout, Lumbago, Influenza and all Feverish Conditions, Colds, Catarrhs, Bronchitis, Headaches and Neuralgia.

Analgesic.—Litmopyrine speedily allays the muscular and joint pains of influenza, as well as of Rheumatic and Gouty Disorders and promptly relieves Headaches.

Complete Solubility of Litmopyrine in water and alcohol permits of its administration in syrups, infusions, tinctures and all other alcoholic or aqueous solutions, where in Litmopyrine is exhibited in a form to ensure its immediate absorption and full activity.

Litmopyrine is supplied in Powder form in 5-grain Tablets, and as a Granular Effervescent.

Samples and Descriptive Literature sent post free to Medical Men by the Sole Manufacturers of Litmopyrine,

ALFRED BISHOP, Ltd., 48, Spelman Street, LONDON, E.1.

The 12 h.p. ROVER SALOON. Price £275.

Send for Catalogue illustrating all Models.

THE ROVER COMPANY, LIMITED, COVENTRY,
59a, New Oxford Street, London and Lord Edward Street, Dublin.

THE variable conditions of road and weather at this season of the year impose severe tests upon the qualities of a car—but the 12 h.p. ROVER Saloon illustrated will prove its superiority. It may be purchased with every confidence to provide comfort in service and absolute dependability—real carriage comfort under all climatic conditions. Many improvements in the chassis have been effected for 1922. A new engine developing considerably more horse-power is fitted, giving greater liveliness and more speed to the car. The lubrication of the engine has been altered to pressure l.o.d.

Morris Oxford Coupé.

The Latest AURORASCOPE Novelty.

(DEES) OPHTHALMIC-URETHROSCOPE.

With this Attachment combining the well-known Electric Fundus Aurorascopes by which a Novice can see the Optic Disc and every detail of the Fundus Oculi, every detail of the Urethra can be brought into focus by means of the Ophthalmic Lenses with the greatest ease, no skill being required. Further, examinations can be conducted under Air-Pressure and treatment carried out in the orthodox manner.

The price of the Urethroscopic Attachment only is £3 3s, complete with probe, Two Endoscope Tubes and Air Bellows, The Ophthalmic-Urethroscop combined in case £8 6s, complete.

Direct Orders at present can only be supplied in priority of application.

PROCEEDINGS OF SECTIONS.

SECTION OF SURGERY.

Professor H. ALEXIS THOMSON, C.M.G., M.D. Edin., F.R.C.S.,
President.DISCUSSION ON
THE DIAGNOSIS AND TREATMENT OF
CHOLELITHIASIS.

OPENING PAPERS.

I.—RUTHERFORD MORISON, F.R.C.S.,

Emeritus Professor of Surgery, University of Durham.

DURING the last twenty-five years there has been an enormous output of literature on the subject of cholelithiasis and its treatment. My interest in the subject extends back more than thirty years, and my first paper bearing on it was published in the *British Medical Journal* in 1894. The title of it was "The anatomy of the right hypochondrium relating especially to operations for gall stones." The fashionable operation of that time was done through a vertical incision in the linea semilunaris sufficiently large to admit two fingers; the operation I advocated was to be carried out through a transverse incision of sufficient size to enable the whole field of operation to be fully and easily explored. This and other papers can be found in vol. II of *Surgical Contributions*, and the page references throughout are to this book of mine.

My next paper complementary to this was published in the *Annals of Surgery* for August, 1895 (p. 141 et seq.), and it has been with some dismay that I have discovered on rereading it how small are the additions I have been able to make since to my knowledge of the subject. I will first quote the conclusions arrived at then, omitting the notes of the cases upon which they were based. Further conclusions extracted from papers which followed, along with a short note of any additional information I have since acquired, will provide a complete history of my beliefs concerning gall stones up to date.

There are still many questions unsettled and unsolved, so that discussion should be useful if each one taking part in it contributes something from his own experience.

1895.

My 1895 conclusions were as follows (p. 141):

"Gall stones are formed in the great majority of cases in the gall bladder. Mucus seems to be essential to their formation, and this is only secreted by the gall bladder and larger ducts. The circulation in the larger ducts is so constant that deposition of salts and inspissation of bile would be difficult there, but in the gall bladder the relative stagnation and other conditions are favourable to gall stone formation. Though gall stones are not infrequently found in the smaller bile ducts, it does not follow that they are formed there. It is not difficult to believe that they are carried and deposited by a back-flow of bile, which must be a common occurrence in the complicated biliary circulation."

"My belief is that the pain of gall-stone attacks is due to the presence of a stone and cholecystitis. Neither stone alone nor distension alone causes contractions of the gall bladder, which are the cause of the painful attacks."

Diagnosis.

"Painful spasms" commencing in the epigastrium are the earliest symptom of gall stone. These are due to forcible contractions of unstriated muscle, probably stimulated by cholecystitis. A stone small enough to obstruct partially the cystic duct causes some distension of the gall bladder, which can be palpated, and the disturbance intermits.

"When the gall bladder is distended without jaundice, and pain after the first acute attack is absent, a stone has completely blocked the mouth of the gall bladder or the cystic duct. Such a gall bladder can continue as a painless

swelling for weeks or years if its mucous membrane does not become infected."

"Attacks of severe pain in the epigastrium and right hypochondrium, accompanied by vomiting and shivering and followed by sweating, complete relief, and transient jaundice, are due to the passage of a gall stone from the gall bladder through the ducts into the duodenum."

"If relief after the pain is incomplete, the jaundice more or less persistent, and the patient every now and again attacked by ague-like paroxysms, generally with, or perhaps without, pain, each attack being followed by a temporary increase of jaundice, a stone is impacted in, but not completely blocking, the common duct. Operation in these cases shows a much dilated common duct and a small contracted gall bladder. The dilatation of the duct is what surgeons who know of the behaviour of all muscular ducts with foreign bodies in them would expect. At first the intruder is firmly gripped, but shortly dilatation commences, and the walls of the tube tend to recede more and more from it. The gall bladder in the early stages can be felt enlarged and tender; in the later stages the local signs are tenderness and enlargement of the liver, for then the gall bladder is shrunken and thick-walled, and generally buried in adhesions. Like the urinary bladder the gall bladder will become contracted and hypertrophied when dealing with a partial obstruction, and, like it, will dilate painlessly when its efforts to overcome the obstruction are futile."

Treatment.

Gall stones are a serious possession, and only operative measures are of any real use. The diagnosis of gall stones should consequently mean the recommendation of an operation, because this is safer than expectancy; recovery after operation is expeditious and complete in cases uncomplicated by delay, and the suffering of patients operated upon is incomparably less.

The operation advocated by me opens up by a transverse incision extending from over the rectus muscle in front to the loin behind, midway between the costal margin above and the iliac crest below, the pouch I described in 1894. This gives free access, allows of the best drainage, and is seldom followed by hernia.

1. When the gall bladder is not contracted (after removing all stones) the opening in it should be closed by sutures and the viscera returned to the abdominal cavity with drainage of the pouch.

2. When the gall bladder is shrunken it may be returned unclosed.

3. When a stone is impacted in the cystic duct and evades all ordinary efforts to remove it, the gall bladder should be excised and the cystic duct ligatured.

4. When a stone is impacted in the common duct, the duct should be incised, and after the stone or stones are removed the opening may be left unclosed if there is any difficulty in applying a satisfactory suture, as drainage of the hepatic pouch behind will suffice.

5. When a stone is impacted in the common duct, it depends upon what part of the duct it is lodged in, whether finding it during the operation is difficult or easy, and its removal safe or complicated. The stone may be lodged above that portion of the duct which comes into relation with the head of the pancreas, when it can be grasped and removed by a direct incision, after exposure of the portion of duct in which it is lying, the separation of (often troublesome) adhesions being the chief difficulty; or it may be lodged in the ampulla of Vater, where it is entirely covered up by the head of the pancreas, and interferes with the flow from the pancreatic duct. Inability to feel the stone and the induration of the head of the pancreas in such a case may lead the operator to believe that he is dealing with a pancreatic tumour. If, after opening the duct, a stone cannot be removed through the ordinary incision, it should be taken out through the duodenum, as recently advised by McBurney.

6. The gall bladder should never be sutured to the parietes.

7. If the usual operations are followed by the fresh formation of gall stones, resection of the gall bladder must be the rule.

1897.

In 1897 (p. 241) I drew special attention to cases in which a painless gall-bladder tumour and painless jaundice might mislead if the early history of pain had been forgotten, and also recorded a case of sacculus of the gall bladder, pointing out the possibility of rupture into the peritoneum, which I believed was a not uncommon event in gall-stone cases.

1898.

In 1898 (pp. 289-299) the importance of a gall-bladder tumour and its differential diagnosis was pointed out.

"Proof that gall-stone pain is due to contractions of the gall bladder is found in the facts that prolonged distension of

it produces no pain; that the closure of a fistula, if the obstruction be not removed, is followed by pain immediately relieved by discharge from the fistula, and that the injection of such a fistula with fluid distending the gall bladder produces characteristic gall-stone pain, just as tension from injection of the kidney pelvis produces renal colic.

"After an attack the bowel excreta should be carefully searched and if stones are found this is an encouragement to wait, but even then the wait must not be prolonged. If no stones are found, and the attacks are repeated, it is probable that a stone is impacted, and the sooner it is removed the better.

"In jaundiced cases the discovery of adhesions, which often point to old ruptures of the gall bladder, during the operation is of considerable diagnostic value and important because they are an encouragement to continue a search for stones."

1903.

In 1903 (p. 491) is a record of cases dying after operation, showing that the mortality chiefly depended upon delay resulting in the pathological changes which had occurred in the liver and ducts—hepatitis, cirrhosis, and cholangitis.

1905.

In 1905 (p. 652-671) "that serious results are scarcely at all due to the hundred more or less stones in the gall bladder but to one or more driven into the ducts" is emphasized.

That complete obstruction, with an active inflammation superadded, resulted in tension gangrene—that is, gangrene commencing at a spot most remote from the source of the vascular supply, such as could occur in every hollow viscus.

That sacculi were common to all of these hollow muscular viscera.

That pancreatitis in some cases so closely simulates gall-stone attacks as to make diagnosis impossible. In many of these cases the intermission of the pains and jaundice can only be explained by the view that a temporary increase of the pancreatic swelling causes for a time obstruction of the common duct, and this explains the fact, which I have not seen previously noted, that the gall bladder may be thick-walled and contracted, whereas when the obstruction is complete, as in cases of pancreatic tumour, the gall bladder is thin-walled and distended and the jaundice permanent. During operation the size and condition of the gall bladder may be of considerable diagnostic value in these pancreatic cases, for it is impossible from examination of the hard enlarged nodular pancreas to say whether the infiltration is due to malignant or inflammatory deposit. A small bladder favours the diagnosis of simple, a large one that of malignant change in the pancreas.

When a single good-sized stone is present in the contracting gall bladder it may be driven into, but not impacted in, the neck and fall back when contractions cease.

If a large stone completely blocks the gall-bladder neck the attack is attended as a rule by unusually severe and long continued pain, which only gradually abates. Sooner or later after this attack the swollen, tense gall bladder will be discovered as a tumour under the right costal margin.

The case may then assume one of three types:

1. The condition is chronic, and the gall bladder is distended with clear fluid (hydrops of the gall bladder). In this case I suggest that the gall bladder had emptied itself before the stone became impacted, and that the mucus filling it and secreted by its wall, possessed, as all mucus secretions probably are, of some antiseptic quality, had destroyed any infection which might be present.

2. The distended gall bladder contains pus (empyema of the gall bladder). The diagnosis is based chiefly upon the tenderness of the tumour, which never disappears; and upon its becoming later more indefinite in outline, from omentum adhering around it.

3. In the most severe type, a few hours after the commencement of the illness, the swollen, very tender, and tense gall bladder may be felt as a hard tumour, the patient looks very ill, and there is a frequent complication (gangrene of the gall bladder). In these cases the gall bladder is found to be infected, dark-coloured bile. It must have been null or thus at the time impaction of the stone occurred, and I offer this explanation of the serious result.*

Jaundice and pain may both be absent and stones can be found accidentally in the common duct.

Repeated shivering attacks, without pain, but attended by fever and followed by jaundice, may be the only evidence of gall stones in the common duct.

*D. P. D. Wilkie's experimental results in occluded loops of intestine correspond exactly with the three conditions I had here described in the gall bladder.

Natural cure can occur at all stages of the attacks, and in the most serious cases an imitation of Nature's methods points to drainage alone, or cholecystenterostomy, as possibly the best treatment.

The danger of gall-stone operations is the result of delay and complications.

Operations for the removal of gall stones are most satisfactory when the stones are still in the gall bladder and their escape into the ducts can be prevented.

Shock, hæmorrhage, and sepsis, the dangers common to all operations, are increased in jaundiced patients, and it may be impossible to remove stones from all the liver ducts, where I have not infrequently found them at *post-mortem* examination of neglected cases.

Treatment.

During the operation it is important to feel the neck of the gall bladder and the main ducts between a finger and thumb introduced into the liver pouch and the foramen of Winslow.

If the gall bladder is emptied of stones, there are none in the ducts, the cavity and walls of the gall bladder look fairly healthy and the cystic duct is patent, the gall bladder should be completely closed and returned to the abdomen with a small tube drain in the hepatic pouch. Patency of the duct is assured if, during operation, bile escapes back into the gall bladder; if not, it can be tested by pumping saline from the gall bladder into the duodenum.

If the illness is recent, and the cystic duct is obstructed by what is probably temporary swelling, or if there are signs—such as thickening, reddening, or presence of surrounding adhesions—that its walls are infected, the gall bladder should be drained.

After removing all palpable stones from the common duct it should be fully explored if possible by a finger, or with a thick metallic probe. This should be first passed upwards into the hepatic ducts, then downwards into the duodenum, to assure as far as possible that all stones have been taken away.

If stones are discovered in the hepatic ducts all that are easily accessible should be removed, but no prolonged or serious manipulation should be indulged in. Drainage must do the rest.

In the most acute cases, with gangrene of the gall bladder, after removal of the stones drain freely, with as little disturbance of the enveloping omentum as possible. Excision of the acutely infected gall bladder adds a serious risk to the operation.

In 1910 I operated upon a high-livered, short, fat, muscular man who required cholecystectomy. The physiological difficulties of performing the operation in the ordinary way were forbidding. Instead, I laid the gall bladder open from fundus to cystic duct, destroying what remained of its lining membrane with a thermo-cautery, put in a tube, and sutured the outer coats over it. He made such an easy recovery that I have since performed the operation on more than twelve occasions. All of the patients recovered, and I have heard of no recurrence in any of them.

CONCLUSIONS IN 1922.

To sum up latest conclusions I start with *Etiology*.

A great many explanations have been offered for gall-stone formation. The most universally popular has been, and perhaps still is, that they are all due to infection of the gall bladder. There is sufficient evidence against this view to condemn it. Until the cause of calculus formation everywhere in the body can be explained—and the explanation is likely to come from chemists—doubts as to the etiology of those in the gall bladder will not be dispersed. Some predisposing causes are more common than others—for example, repeated pregnancies, obesity and a sedentary life, a previous attack of typhoid fever (now a rare disease in this country); but in my experience the most common of all is that the patient is an abstainer from fluids, either by taste or prejudice, so that women and teetotalers are frequent victims.

So much depends upon knowledge of the behaviour of the gall bladder that a short note on this may be useful.

There are now doubts raised by some laboratory workers as to the possibilities of contraction of its wall, judging by their experimental research and histological examination. In my earliest cases, and often since, I have removed portions of the walls of gall bladders which contained stones and given them to a competent histologist. He found, when the walls had not been destroyed by inflammation, that the thickening was due to an increase of the muscular coat.

The smooth facets on multiple stones, and the occasional fracture of oven hard stones in the gall bladder, are further evidence of the power an irritated gall bladder may exercise.

The strongest evidence is clinical, and an early experience taught me a valuable lesson.

About thirty years ago I assisted the late Professor Pagenstecher with an operation on one of the older sisters in the infirmary. She had had many attacks of gall stones, and had in her possession a large collection evacuated naturally at different times. Lately the attacks were increasing in severity and frequency to such an extent that immediately after the last one she decided to have an operation, as she had heard that this was now possible. On opening her abdomen the gall bladder was seen to be about the ordinary size, was free from adhesions, but thick and red. Neither Professor Pagenstecher nor I could feel any stones, either in it or in the thickened duct, and we ventured to hope she must have passed the last one. Three days later a stone of the usual shape and size, something like a faceted horsebean, was recovered from the first faecal evacuation, and the patient had no further recurrence of her attacks during the time she was under observation—more than five years. To pass stones of this size through a duct the size of the cystic, and to impact so tightly in the neck of the gall bladder such large stones as are found there, demands some muscular activity.

No one with experience and an impartial mind can doubt that gall stones may lie for long periods without producing symptoms either in the gall bladder or, though rarely, in the common bile duct. It can also be said that certain stones are more unlikely than others to offer evidence of their presence.

There are, as in the kidney, three clinical types of stone:

1. Multiple, small.
2. Medium, a few or single.
3. Giant stones.

The multiple, small variety, from the patient's point of view, gives most trouble both in gall-bladder and kidney cases, because these stones are apt to escape into the ducts and pass through them, producing urgent temporary symptoms and repeated attacks. Medium stones, say of the size of a hazel nut, in gall bladder and kidney are apt to cause a sudden obstruction by blocking the outlet. Giant stones in either locality cause no typical symptoms, and are generally discovered when complicated by a serious infection, and, in the case of the gall bladder, by intestinal obstruction.

Diagnosis.

There is only one subjective symptom on which a diagnosis of gall stones can reasonably be based, and that is *pain*—but it must have special characteristics. It should be *severe*, often so sudden in onset as to be compared to a stab, lasting only a few moments in some cases (especially those with single rounded stones), in others for hours, referred to the epigastrium, catching the breath before inspiration is complete, and on its cessation leaving the patient entirely well. It often awakens the patient at night, like all colics, and is ascribed to some particular food, is frequently followed by vomiting, and is called "indigestion."

A tender area over the gall bladder on deep palpation during forced inspiration, discovered during the attack of characteristic pain, and lasting for a time after it, form the ordinary reasonable grounds for a diagnosis of gall stones, and will be correct in eight cases out of ten.

When all stones have escaped from the gall bladder into the common duct, attacks of pain, but less violent, still usually occur.

Of the signs, a gall-bladder tumour or jaundice preceded by a typical attack of pain are clinical guides that seldom fail. In my experience, in 29 of 30 cases the gall-bladder tumour is due to obstruction by a large stone; in 18 of 20 cases the pain and jaundice are due to a stone forced into the common duct.

It is likely that no great advance in diagnosis will be made till x rays demonstrate gall stones in the bladder and ducts as they now do in the kidney and ureter.

Treatment.

The knowledge that there is only one reasonable treatment—namely, operation—is even yet not sufficiently realized, but there is an enormous improvement in this respect, as in the results of operations, on twenty-five years ago.

Since surgeons learnt that abdominal operations cannot be performed properly with two of their fingers in the abdomen

and their eyes on the ceiling many new abdominal incisions have been suggested for the removal of gall stones, and though I am not going to say that my own is the only one to be considered, or the best, I know that it is so for me. In addition to the advantages, especially drainage, already mentioned, I would add that only the eleventh intercostal nerve is divided by this incision, and that opening up a limited area, such as the pouch described, produces less disturbance than such a free exposure of the general peritoneal cavity as is necessitated by any other, if the vermiform appendix be examined, as it always should be.

Recurrence of gall-stone attacks and the external fistulae, either mucous or biliary, occurring after operations are still frequently due to stones left behind, and sometimes from insufficient exploration, which it is impossible to make efficiently through an inadequate incision.

Good results are likely to follow all careful operations for the removal of gall stones, but recurrence has followed skilful cholecystotomy, cholecystostomy, or cholecystectomy, and every experienced surgeon knows this. He does not yet know the pathology and bacteriology of gall bladders and bile ducts in which this is likely or unlikely to happen, and to settle this will require more patient research. Until this knowledge has been acquired rules for operative guidance cannot be satisfactorily laid down.

Since my earliest paper and in every later one I have advocated cholecystotomy as the best operation when the cystic duct was patulous, and this is still my conviction. In the January and February numbers of the *Annals of Surgery and Gynecology, and Obstetrics*, 1922, are two papers by distinguished American surgeons, advocating the "resuscitation" of this neglected operation, so that it is possible more may be heard of it. I have never closed the abdomen entirely, but have left a small tube drain in the hepatic pouch, because many years ago a small leak occurred in one of my cases, and I prefer to take no risks.

If the gall bladder be seriously infected it should be opened freely, the stones removed, and its walls and its interior carefully inspected—unless it is so obviously pathological that recovery seems impossible it should have the benefit of the doubt. I know, from opportunities of inspecting it later, that it can recover from almost hopeless-looking conditions of disease if given a chance by removal of stones, followed by drainage through a tube maintained in position by a water-tight catgut suture. If bile discharges freely from the tube it should not be kept in for more than a few days, and never for more than two weeks. The one disadvantage of this operation is that in a small percentage of cases, though every stone be removed a second operation may be required for recurrence of symptoms, but this possibility should be faced. A second operation on the abdomen shows that the first has increased the natural peritoneal immunity to such an extent as to make the consequences of the second of considerable less importance.

If the gall bladder is so much diseased that its recovery seems impossible it may be dealt with by cholecystectomy or the thermo-cautery.

My present views are against cholecystectomy as the operation of election in gall-stone cases. Just here again I want to compare the gall bladder with the urinary bladder. Every surgeon expects that after removing a stone from the urinary bladder a cystitis accompanying it is likely to disappear very soon; he also realizes how difficult it is to get rid of a cystitis without stone. I believe the same to be true of the gall bladder, and that for a calculous cholecystitis removal of the stone may suffice, but that cholecystectomy may be the operation of election for a primary cholecystitis. The dangers of the actual operation may be dismissed, as in capable and experienced hands they should not be greater than from any other gall-stone operation; my objection to it arises from physiological considerations (gall-bladder functions) and the after-results in some cases. Patients upon whom this operation has been performed may afterwards develop attacks which, they say, are similar to their old ones. After a time they become jaundiced, a difficult and dangerous operation is performed, and no gall stones are found. The common duct is thick-walled and dilated, the liver looks fibrous, and that is all the discoverable gross pathology. Further evidence will require time to collect, for in one of the cases in which, ten years earlier, I had done cholecystectomy and cholecystostomy and drained the common duct, the patient was well for seven years, and not until ten years had elapsed after the first operation did she become ill enough to require a second.

It may be laid down as a general principle that the ducts of the body possess a protective mechanism which is of considerable value to the viscous with which they are connected. It is well known from experimental and clinical evidence that dilatation of the common duct follows cholecystectomy. This upsets the protective mechanism of a duct opening into a potentially septic area—the duodenum—and this cannot, I think, be done with impunity.

It is likely that a new form of hepatic cirrhosis is in course of development since the surgical craze for cholecystectomy has become widespread.

Since the beginning it has been recognized that patients with jaundice, especially when deep or prolonged, are liable to die from haemorrhage oozing, in spite of the occlusion of all visible blood vessels at the time of the operation.

If tests of the blood show that it does not coagulate in less than eight minutes means should be adopted before operation to avert this. For many years calcium preparations have been used for this purpose, but doubts are still entertained as to their efficiency. It seems probable that transfusion of blood a day or two before the operation will now receive a fair trial.

When stones have been removed from the common duct I have, during later years, drained it with a tube sutured in, though my early practice of leaving the gall bladder and duct incisions open and draining the hepatic pouch only was successful. Acting on an American suggestion I have left an india-rubber catheter in the same duct opening and passed through into the duodenum for the introduction of fluid and nourishment in specially weak patients, with, I feel sure, considerable advantage. Drainage tubes should not be left in for more than two weeks, when efficient natural drainage should have been established. Retained tubes are more likely to increase than to decrease any existing infection.

In one very rare case I operated upon in 1903 the patient, a man of 63, had been afflicted by gall stone attacks for five years, and on admission was very ill and slightly jaundiced. On opening his abdomen the gall bladder was found to be large, thin-walled, and much distended, and his common duct was as large as his duodenum. Both gall bladder and common duct contained several large stones and clear fluid quite unlike bile—the so-called "white bile." There was no blocking of the cystic duct. A radical operation was done; all the stones were removed and the gall bladder and common duct were drained. Nine days after operation the patient died—the necropsy showed from septic infection. If the condition of this patient had been realized when his gall bladder, free from obstruction, was found to be full of "white bile," and whether or no his common duct had been explored with a small needle to discover if similar contents were to be found in it, all attempts to do a radical operation should have been abandoned, and the gall bladder drained through a small tube. He would then have had a fair chance to recover temporarily. If, later, bile had been discharged through the tube in sufficient quantity, the operation should have been completed, as is now done in prostatic cases with a similar outlook.

In conclusion, I would like to raise an objection to the various textbook descriptions of cholecystitis. The terminations of cholecystitis are the same as the end-results of inflammation everywhere in the body. They may be catarrhal, or ulcerative, or phlogmonous, or suppurative, or gangrenous, or anything else adding to the difficulties of understanding them, but that should cease to be the teaching of writers who are to train the younger surgeons.

II.—FARQUHAR MACRAE, M.B.,

Surgeon, Western Infirmary, Glasgow.

For the formation of gall stones in the gall bladder there seems little doubt that two factors are essential—namely, bacterial infection and a degree of stasis. In no experimental work has it been found possible to produce definite concretions without the combination of these two conditions.

It seems just possible that pure cholesterol stones, or more commonly a single cholesterol stone, may develop in the gall bladder in the absence of infection. While experimental work gives no support to this view, and indeed tends to throw doubt on the possibility of its occurrence, the clinical history of cases in which such a stone gives occasion for surgical intervention clearly gives support to the view that such stones may be formed without any contamination of the bile by bacteria. Unlike the mixed gall stone the pure cholesterol stone gives rise to no premonitory symptoms

before a block in the cystic duct takes place, and the hydrosis of the gall bladder which follows is never associated with the development of an empyema of the gall bladder.

There is, of course, the possibility that, at the beginning of the development of such a stone, there may have been infection which has subsequently been washed away from the gall bladder by the flow of bile; but in these cases the invariable absence of prodromal symptoms before the cystic duct is occluded and the freedom from development of pus in the gradually distending gall bladder make this rather an unlikely hypothesis. The great majority of the cases of cholelithiasis which require consideration by the medical man belongs to the class in which the stones are mixed in character, and there seems no doubt that in all of them the two factors of infection and stasis are present, at least at the beginning of the formation of the stones.

In test tubes cholesterol has been precipitated from normal bile to which have been added bacteria, especially *B. coli*, and there seems little doubt that the deposit of the main cementing substance, calcium bilirubin, depends on the precipitation of this substance from bile by the excess of mucus which is excreted as a result of a catarrhal condition of the gall bladder. The exact course of the infection has been a subject of much dispute, the majority of those who have written on the subject claiming that the mode of infection is by way of the portal circulation and liver to the ducts and then the gall bladder, while others believe that the infection takes place directly from the systemic circulation. It is possible that both modes occur; but there seems no reason to doubt that in the great majority of cases, if not in all, the infection of the gall bladder takes place by way of the ducts.

It has been proved experimentally that animals fed on material contaminated by bacteria, and in whom the common duct has been ligated, will within a few hours give cultures of the ingested bacteria from the gall bladder and ducts. That this is not an accidental contamination unassociated with the ingestion of bacteria has been fairly conclusively shown by the use in these experiments of *B. pyocyaneus*, which is not under ordinary circumstances found within the bile passages.

It is, of course, true that micro-organisms present in the general circulation can also be obtained in the gall bladder and bile ducts; but this in no way negatives the view that they reach these places through the avenue of the portal vein and liver. Two features, which do not appear to have been emphasized, seem to me to point more directly to the latter being the usual mode of entrance. The first is that in order to give rise to a stone-forming catarrh in the gall bladder the bacteria require to be attenuated, and it seems likely that this process of attenuation most probably occurs during their passage through the liver. The other is the infrequency with which abscesses develop in the wall of the gall bladder, even when the wall is greatly thickened. In about 500 gall bladders with which I have had to deal I have only seen two in which this had occurred. In both cases the gall bladder was much thickened and in both the abscesses were multiple, and therefore an embolic origin was suggested. In both also the offending micro-organism was *B. coli*; but in neither were there any symptoms to suggest a septicaemia, and in both the removal of the gall bladder led to the immediate disappearance of all symptoms. It is quite possible, therefore, that, even in these cases, the infection which led to the development of the abscesses took place not through the blood circulation but by way of the lymphatics. If the infection of the gall bladder took place at all frequently through the systemic circulation one would expect to find much more frequently than one does abscesses develop in the wall of the gall bladder where it has been much thickened.

Another fact which points strongly in favour of the view that the bacteria reach the gall bladder by way of the ducts is the frequency with which pancreatitis is associated with the cholelithiasis—the inflammation being limited as a rule to the part of the organ which is in most direct connexion with the bile ducts. Direct infection upward from the duodenum has been held to play a part in the infection of the gall bladder, and it has been shown experimentally by Bowd that such a process can occur. On the other hand, no part of the bowel is normally as free from infection as the duodenum; indeed, it is probably sterile save when food is passing through, and during the time that this is occurring there is an intermittent expulsion of bile which presumably will prevent any invasion of the common duct from the bowel. Taking everything into consideration, there seems every reason to believe that the usual, if not the only, mode of introduction of the infection is by way of the portal circulation and liver.

The origin of the stasis of bile is not so readily understood. It may be due to any condition which increases the viscosity of the bile, or to any interference with the calibre of the ducts from external pressure or from kinking. That the former condition is probably a main factor in some cases is, I think, shown by the very much greater frequency with which gall stones are said to be found in the post-mortem room in individuals dying from heart disease than in those who die from other causes.

In the majority of cases this undue viscosity of the bile does not appear to be the main cause, and one must look for some external source of interference with the flow of bile in the ducts. It appears to me to be likely that the suggestion of Waugh that this cause may be found in the drag of a mobile ascending colon will be found to be the probable explanation in the great majority of cases. It is certainly noteworthy that the majority of the usually accepted predisposing causes of gall stones are all such as tend to exaggerate any ptosis which may be present. All of them are such as to lead to diminution in the tone of the muscular wall of the abdomen, and thus, by allowing a prolapsed colon to sag further, will be likely to lead to more or less kinking of the bile ducts.

In the case of one of the commonest predisposing causes—pregnancy—it is quite possible that the increased cholesterol in the blood and the direct pressure upwards of the gravid uterus may be important factors; but the infrequency with which gall-stone colic occurs during the course of pregnancy appears to me rather to negative the view that direct pressure takes much part in interfering with the flow of bile. It is more likely that repeated pregnancy acts by the ptosis of the abdominal organs which supervenes on labour leading to kinking of the ducts. Very much in support of Waugh's view is the undoubted fact that recurrent attacks of cholecystitis may entirely cease in such cases after the ascending colon has been fixed in accordance with his method. Since he drew attention to this possible cause for the relative stasis of the bile, I have noted the condition of the colon in all of the cases of gall stones on which I have had to operate, and in all the ascending colon has been unduly mobile. It appears to me that we have in this suggestion the probable explanation in the majority of cases of the second factor, relative stasis of bile, in the etiology of gall stones.

A well-developed case of cholelithiasis presents no particular difficulty in diagnosis if seen during the hepatic colic. The character of the colic, coupled with the site of the pain under the right costal margin, radiating to the back, and the tenderness in the same situations usually make the diagnosis one of little difficulty, especially if, as is usual, there is some degree of dilatation of the gall bladder, sufficient to render it palpable even under the rigid upper right rectus. The only conditions which could readily simulate it are perforation of a pyloric or duodenal ulcer, renal colic from stone or from infection with *B. coli*, appendicitis, acute pancreatitis, or pancreatic calculus.

In differentiating between hepatic colic and gastric or duodenal perforation the characters of the antecedent dyspepsia in cholelithiasis, to be spoken of later, are of the very greatest importance; but, even without such a history, which in the condition of the patient may not readily be obtainable, the local signs, if they are carefully observed, are such as to make a mistake unlikely. First in importance is the extent of the rigidity of the abdominal wall. In every case of perforation of gastric or duodenal ulcer into the free cavity of the peritoneum, in the early stages and for some hours after the onset the whole anterior muscular wall of the abdomen is rigid and board-like and gives no relaxation at the end of inspiration or expiration. On the other hand, in hepatic colic, as in all cases of limited peritoneal irritation, the muscular rigidity is limited to an area corresponding to the inflamed peritoneum and gradually fades as one tests it by moving the pressure away from the area implicated.

In hepatic, as in all other colics, the patient does not lie quiet and resent movement, but tends to toss about seeking, but not obtaining, relief to his distress; whereas in perforative peritonitis involving the upper abdomen the patient lies quietly on his back, usually with his legs drawn up, and never tosses about. If the patient be turned on his side and heavy percussion be made to the right of the spine from above downwards as one approaches below the angle of the scapula a sudden acute exacerbation of discomfort, often felt most pronouncedly in front, will be found to take place in every patient suffering from hepatic colic, while no such

localized alteration in the amount of discomfort will occur in perforative peritonitis.

Should vomiting occur it is more likely to be repeated in hepatic colic than in perforative peritonitis, and whereas in the latter it has little effect on the pain, except to aggravate it at the moment of emesis, in the former it is quite usual at and immediately after the act of vomiting to have the pain moderated or even to have it disappear entirely, only for it to recur within a few minutes with its original intensity. Further, the pain in perforative peritonitis is never so characteristically colicky in character as is the case in hepatic colic; usually, indeed, the intensity of the pain does not vary except with change of position or on manipulation of the abdominal wall.

Renal colic, whether depending on calculus or on infection of the pelvis of the kidney with *B. coli*, may simulate hepatic colic quite closely. In neither of these renal conditions need there be, though there usually are, other signs or symptoms suggestive of infection of the urinary tract, nor is it invariable, particularly in *B. coli* infection, to have the pain radiate down the course of the ureter. It is in cases such as those that the difficulty will arise, but even in them the two varieties of colic may be distinguished usually without difficulty. If the back be percussed in the fashion mentioned above it will be found that in hepatic colic the site where percussion gives rise to greatest pain is just under the angle of the scapula, whereas in conditions giving rise to colic originating in the pelvis of the kidney the site of the greatest pain is at a distinctly lower level over the last two ribs. Direct pressure, in the case of an inflamed gall bladder, is most painful just under the right costal margin in front or midway between that and the umbilicus; but in renal conditions the tenderness is most pronounced when pressure is made behind and just below the last ribs. In *B. coli* infection of the pelvis of the kidney, which is more frequently unassociated with other urinary symptoms than is calculus, examination of the urine will always show the presence of the micro-organisms though there may be no pus or albumin. In renal conditions no history of preceding dyspepsia is to be obtained, while in almost all cases of hepatic colic there has been, previous to the acute symptoms, a more or less prolonged story of gastric disturbance.

Appendicitis should not, except rarely, give rise to difficulty in diagnosis, even when the disease is associated with an imperfectly descended caecum. The real difficulty is that very occasionally the pain in gall-stone colic radiates to the right groin, and thus may mislead the unwary. In appendicitis it is very unusual for the acute pain to start with such dramatic suddenness as is the rule in hepatic colic. When the pain becomes localized it does so at a much lower level than is the case in gall-stone colic, and the site of maximum tenderness is similarly placed. There is no exaggeration of the pain by percussion over the angles of the ribs below the scapula, and vomiting does not relieve the pain of appendicitis, but rather tends momentarily to aggravate it. Further, recurrence of vomiting, though not so prominent a feature as in pancreatitis, may and frequently does take place during severe hepatic colic, whereas this is very rare in appendicitis unless the general peritoneal cavity is widely involved in the inflammation, and before this has had time to occur a correct diagnosis should be assured.

Acute pancreatitis presents particular difficulty because of its frequent association with the presence of gall stones in the gall bladder, often indeed with preceding overt manifestation of their presence in the shape of previous attacks of hepatic colic. The pain in this disease, though frequently colicky in character, remains localized to the epigastrium and left hypochondrium and never passes to the right costal margin. If it shoots towards the back it is always to the left of the middle line and not to the right as in hepatic colic. Vomiting is an early symptom, and is so frequently repeated that it simulates that occurring in intestinal obstruction rather than what obtains in hepatic colic. It is associated with persistent nausea, and the act of vomiting does not at all frequently give even temporary relief, in both these respects differing from what usually obtains in hepatic colic. The rigidity is limited to the same area as that affected by the pain, and is epigastric or under the left costal margin. It is never so pronounced as over an inflamed gall bladder, and is usually so comparatively that under the abdominal ing roughly in shape and distribution with the distended inflamed pancreas. Pressure in the left costal-iliac space, if

present, as it is said to be not infrequently in acute pancreatitis, would be a complete proof that one was not dealing with a case of hepatic colic. In pancreatitis the collapse which is present is associated with cyanosis, sometimes with mottling of the abdominal wall, whereas the collapse associated with hepatic colic is accompanied by pallor.

Pancreatic calculi do not present many symptoms that enable one to differentiate between them and gall stones. I have never seen, or at least never recognized, such a condition; but it is said that the pain is referred to the left side rather than to the right, that in a large proportion of these cases there is intermittent or constant glycosuria, and that in a large percentage of such cases, in the absence of jaundice, calcium oxalate crystals are found in the urine. The only method which enables one to distinguish absolutely between the two conditions is the use of the x rays. It is rare by this means to get evidence of the presence of gall stones, whereas pancreatic calculi always give a dense shadow.

While a well-developed case of cholelithiasis presents symptoms that unmistakably point toward the source of the trouble, it is only in a very small minority of cases that one gets anything approaching hepatic colic in patients who yet are troubled with gall stones. In practically all patients who are the subject of gall stones careful inquiry will elicit a history of preceding persistent indigestion of longer or shorter duration before the onset of colic, and all patients who are subject to attacks of hepatic colic will be found in the intervals to be constantly troubled with indigestion which presents fairly characteristic features.

The main features which characterize the indigestion of gall stones, and which usually enable one to distinguish it from a similar condition arising in the stomach or duodenum, are three in number. First, it is not materially affected by variations in the character of the food ingested; it occurs equally after a light or after a full meal, though it may not be quite so intense; secondly, it is constantly present over long periods, and does not show the longer or shorter remissions of freedom from pain which almost invariably obtain in gastric or duodenal ulcer; and thirdly, it does not recur so regularly at a stated interval after meals, but tends to be variable in the time of onset and may occur through the night.

The character of the indigestion is that of a flatulent dyspepsia, associated with what the Americans very accurately describe as "gas pains," which is so frequently associated with gall stones that patients come to look on it as a normal happening, and in many cases will not mention it unless it is specially inquired for; but if that is done, in my experience, they almost invariably admit its existence. So frequently is it present in gall stones and cholecystitis (though, perhaps, less regularly so in the latter) that I think it may safely be said that the vast majority of well-nourished patients who are constantly and persistently the subject of gastric flatulence either have gall stones or cholecystitis. It is a striking fact that such patients may have this "indigestion" persisting over a period of twenty or thirty years without any interference with their general nutrition, in this respect differing markedly from those who are the subject of gastric ulcer, but resembling a fair proportion of those suffering from duodenal ulcer. Of course, gastric flatulence may obtain in any patient who has a chronically dilated stomach; but these always show evidence, both local and general, of the existence of this condition, and in particular they invariably show signs of malnutrition. Further, when the eructation of gas is due to dilatation of the stomach in the course of a few years the gas tends to be malodorous. This never occurs in the cases due to gall stones.

It is in these less typical cases that Mayo-Robson's observation of a tender spot about midway between the umbilicus and the ninth costal margin in gall-stone disease becomes so valuable. In my experience it is in these "silent" cases of gall stones that one almost invariably gets this sign, while in the more advanced cases with colic the point of greatest tenderness is more frequently just under the costal margin at the most prominent part of the costal cartilage or between this and the xiphoid. Some—though only a small proportion—cases of cholelithiasis are practically indistinguishable from duodenal ulcer. In these, as in duodenal ulcer, pain comes on regularly about two hours after food, and is immediately relieved by the taking of food, and the x-ray picture may not be sufficiently characteristic to enable one to distinguish between the two conditions. It is of course unusual to come across patients suffering from duodenal

ulcer in whom there are not considerable periods of time during which all symptoms are in abeyance or in whom variations in the character of the ingesta do not affect the intensity of the symptoms; but occasionally such cases do occur, and I am not aware of any means by which such cases can be differentiated from the anomalous cases of cholelithiasis in which "hunger pain" is the prominent feature.

The symptoms of the single cholesterol stone, when that does give trouble, are so characteristic as to present no difficulty in diagnosis, since the progressively distending gall bladder is always preceded by hepatic colic of great intensity without any antecedent symptoms, gastric or other, pointing to trouble in the region of the liver. The only error which is likely to occur is to mistake a distended gall bladder for an enlarged kidney—a markedly distended gall bladder always being found pointing outwards and not, as the textbooks say, towards the umbilicus.

TREATMENT.

The radical treatment of gall stones, as distinguished from the treatment of the symptoms in cholelithiasis, is purely a question of when the surgeon should intervene. There is no medical treatment save that which may be directed to diminishing the liability to attacks of colic, or to palliate the dyspepsia which is the sequel to the presence of gall stones in the gall bladder. It is very doubtful whether much can be done that is effective in either direction. There seems little doubt that an attack of colic in the ordinary case of gall stones is the result, not so much of displacement of stones as of an increase of the inflammation in the gall bladder, and it is just possible that a similar statement may be true of the origin of the dyspepsia, though the persistent character of this latter symptom renders this explanation unlikely. The removal of any septic focus, especially if that be located in the area drained by the portal vein, is an obvious indication, and similarly the avoidance of constipation would give some hope that the attacks of colic may be diminished in frequency. Any attempt to render the bile antiseptic by the use of such drugs as urotropine in doses which would not do harm otherwise seems to me to be quite obviously futile, and, laboratory experiments to the contrary notwithstanding, it is very doubtful whether by the use of any drugs the bile can in practice be so altered in consistency as to have any material effect either in altering its amount or its rate of expulsion.

Though no alteration in the character of the food ingested will in most cases entirely abolish the dyspepsia associated with cholelithiasis, this is aggravated by the taking of much green vegetables or of an excess of starchy foods, and these should be avoided.

Admitting that there are no medical remedies which can cure patients afflicted with gall stones, it does not follow that all cases of cholelithiasis demand operation, even if consideration is limited to those in whom the general condition of health is such as not in itself to contraindicate surgical intervention.

The great majority of the victims of cholelithiasis suffer throughout only from indigestion, and if they are willing to submit to the discomfort and inconvenience of this it is doubtful whether the surgeon is justified in urging operation on them. It is quite certainly not justifiable to urge it on such grounds as is contained in the assertion by a well-known and rightly distinguished surgeon, that "the danger of carcinoma alone is five times as great as is the mortality following operations for the relief of simple gall-stone disease." Such an assertion deserves no credence whatever. It is true that his statistics show that the incidence of carcinoma in the cases coming under his care is in that proportion greater than the mortality among those subjected to operation for simple gall-stone disease. But this in no wise justifies such an inference as he makes. Before any accurate decision as to the incidence of cancer in cholelithiasis can be made, it would be necessary to ascertain the total number of individuals who have had gall stones in a certain community and the number of those who have developed cancer in the gall bladder or bile ducts. As the great majority of those who have gall stones suffer merely from indigestion and in many cases probably never consult a medical man for this, or, if they do, are treated for their symptoms without any accurate diagnosis being made, it is obviously impossible for anyone to state what the true incidence of cancer in this disease is.

No doubt if a patient consults a surgeon for more or less long continued indigestion and a diagnosis of gall stones is made it is right that he should be told that the only cure is by way of surgical operation; but it is very questionable to

my mind whether under these circumstances the surgeon is justified in urging the patient to submit to operation.

The position is altogether different where there has been an attack of colic, and still more where there have been repeated attacks of this nature. In the former case, while no doubt in a fair proportion of cases there are gross structural alterations in the gall bladder and infection of a minor grade in the ducts and affecting the head of the pancreas, it is frequently impossible to be quite certain of this; whereas in the latter the more fact of colic indicates a more severe infection in the gall bladder with a much greater probability, if not indeed a certainty, of infection of the ducts and inflammation of the pancreas. A single attack of gall-stone colic, unless the general condition of the patient contraindicates it, is, in my opinion, a good ground for urging operation on a patient, and still more, of course, if the hepatic colic has been repeated. It is difficult for a surgeon to say in what proportion of patients only one attack occurs, but the impression I have gathered from talking the matter over with the only class of the profession who are in a position to know, the general practitioners, is that it is distinctly unusual for a well-marked attack of cholecystitis with colic not to be followed at longer or shorter intervals by others. As repeated attacks, by inducing contraction of the gall bladder and the formation of adhesions, make the operation not only more difficult but more dangerous, it is clearly the duty of the surgeon consulted by anyone who has a well-marked attack of cholecystitis, not merely to advise operation, but to urge it on the patient. It is, of course, true that in the hands of the expert surgeon the mortality from operation in cases of cholelithiasis in the early stages would be small, and if all cases were operated on in this stage it is equally true that the mortality of the cases now operated on, including as it does those with all sorts of complications, would cease to be so high as it is. But it seems to me to be very open to question, in view of the enormous number of people who possess gall stones, whether the total of those who would die if all these were to be operated on would not be greater than is the case with the adoption of less strenuous surgery. In my experience, at any rate, it is unusual for serious complications, other than gangrene or empyema of the gall bladder—in each of which the indications for operation at the time are clear—to occur unless there have been repeated attacks of cholecystitis, and it seems to me that the proper course for the surgeon is to wait until hepatic colic has occurred before he feels justified in urging operative interference, though patients with the minor symptoms should be told that operation will completely remove their symptoms and obviate the possibility of more serious conditions developing. The choice between the two evils should be left to them after the matter has been explained.

Operation having been decided upon, the question of whether cholecystectomy or cholecystostomy should be done must be considered. Where gangrene of the gall bladder is present or an empyema has developed, where the gall bladder is much thickened or has lost its elasticity and is found contracted round stones, where the so-called "strawberry bladder" is present, or where there are stones in the cystic duct, whether impacted or not, there seems little doubt that the only wise course is to remove the gall bladder. If this is not done it is highly probable that symptoms will return in the course of a few months or a year. Under the circumstances noted above, the only condition the presence of which would make one hesitate to perform cholecystectomy would be a well-marked chronic pancreatitis. When that is present the proper procedure would be to do a cholecystenterostomy or cholecyst-gastrostomy if the condition of the gall bladder makes that feasible, or to drain the gall bladder for a long time if it is not possible to make an anastomosis.

When the gall-bladder wall is merely slightly thickened and the gall bladder not materially altered in size the procedure is not so obvious. The consensus of opinion among the best known authorities at the present time is all in favour of the removal of the gall bladder; but before agreeing to follow the advice offered by them it is perhaps worth remembering that these authorities are the same who in the past have published long series of cases of cholelithiasis treated only by removal of the stones and drainage, with perfect cures in all those surviving. I sometimes doubt whether great authorities are always wise counsellors. Largely because of their eminence in some special department of surgery they tend to have sent to them for treatment the more difficult and complicated cases, and I have sometimes thought that as a

consequence of this feature of their practice they sometimes lose a sense of proportion. They seem also sometimes to forget that operative procedures which they can safely perform cannot be carried out with equal impunity by less experienced surgeons.

If it could be proved that the removal of the gall bladder is less likely to be followed by symptoms than is a cholecystostomy then it might be wise, even though the mortality from the former operation is slightly greater, to do the major operation as a routine. It appears to me to be extremely doubtful whether this is the case. Recurrence of stones in the common duct appears to be at least as frequent after cholecystectomy as is their reappearance in the gall bladder after simple drainage has been carried out. That other complications may occur after removal of the gall bladder is, I think, clearly shown by the fact that during the past year I have operated on three cases of acute or subacute pancreatitis within two years of the patients having been deprived of their gall bladders without drainage.

Chronic pancreatitis is so frequent a sequel to cholelithiasis that I have always hesitated to remove the gall bladder where it could be left, lest one should deprive oneself of the only really efficient method of dealing with this condition should it not subside, by making an anastomosis between the gall bladder and the stomach or duodenum. Judging by my own experience of cases which have required to have their abdomens opened at some date subsequent to operations on the gall bladder, I should say that adhesions of a crippling character are more frequent after cholecystectomy than after cholecystostomy.

It is not from statistics collected by surgeons, still less from statistics of their own cases however honestly given, that the decision whether the gall bladder should be removed or not ought to be made. It is the general practitioner, who has to live "round the corner" from his patient after the surgeon is done with him, who alone can give a real statement as to the relative frequency of late symptoms after a particular operation, and it would be a great boon if this matter could be gone into by collecting statistics from a sufficient number of them to decide this question. As it happens none of those with whom I have discussed the subject have displayed any preference for the major operation, while some have been emphatic in the opposite direction. Should it be decided to remove the gall bladder I would advise that this be done beginning at the fundus rather than at the cystic duct. If this rule were followed there would be fewer cases of injury to the hepatic or common ducts than one is inclined to believe occur.

Believing as I do that the real danger in cholelithiasis lies in the infection accompanying it, I have always arranged for drainage alike where cholecystostomy or cholecystectomy has been performed, and for the same reason I have always hesitated to do the so-called "ideal" operation of cholecystostomy notwithstanding the able advocacy of so distinguished an authority as Professor Rutherford Morison.

DISCUSSION.

Mr. D. P. D. WILKIE (Edinburgh) said: Professor Rutherford Morison indicated what great advances have been made in the last twenty-five years in the diagnosis of gall stones. The early reflex digestive disturbances and mild attacks of cholecystitis are now taken to be sufficient evidence to indicate the necessity for operative interference, and we no longer wait for the symptoms once held to be classical but now known to be the evidence of complications which should be anticipated and not awaited. Increasing experience and improved apparatus are now bringing the x-ray demonstration of gall stones into the field of practical diagnosis and ere long I feel sure this will become a routine clinical method. The use of the duodenal tube, while in its infancy in this country, is sure to play an important part in the diagnosis and probably in the treatment of many, and particularly of the more obscure, infections of the biliary passages. Now that we know how to relax the sphincter of Oddi the problem of biliary sand and chronic cholangitis should be simplified considerably.

As in so many discussions on this subject, attention tends to be focused on the question as to whether cholecystostomy or cholecystectomy should be the operation of choice in dealing with cases of gall stones. Whilst we cannot for a moment regard the gall bladder as being an organ without any definite and possibly quite an important function to

perform, we know that it can be dispensed with without any notable inconvenience. We have now very strong experimental proof that infection reaches the gall bladder by the blood stream—that is, by the cystic artery. We know that micro-organisms can frequently be grown from its submucous coat when the bile and the surface of the mucous membrane are sterile. It is this cryptic infection of the wall which prompts removal as opposed to drainage of the gall bladder. The gall bladder has been compared to the urinary bladder, but I think that it were a fairer comparison to say that in this question of infection it occupies an intermediate place between the urinary bladder and the appendix. We do not think of opening the appendix, removing concretions, and closing it again, because we know that the wall is usually infected and damaged. If, therefore, we regard the infected gall-bladder wall as the primary seat of mischief in most gall-stone cases, if further we recognize it as a focal infection, a source from which other infectious, pancreatic and much more distant, may arise, our obvious duty is to remove it unless by so doing we are either adding appreciably to the immediate risk of the operation or are depriving the patient of an alternative biliary channel of which there is some likelihood there may be need at some future date. Accordingly my practice is to perform a cholecystectomy in all cases where the gall bladder is obviously diseased, except those where technical difficulties make it fraught with added risk to the patient, and in those where a dense sclerosis of the head of the pancreas foreshadows a possible secondary obstruction of the common duct for which a cholecystenterostomy might be required. In two such cases in which I had at a first operation removed the gall bladder I would have given much at the second to have had it back again.

Too much has possibly been made of this question of removal of the gall bladder to the exclusion of the more important question of the common duct, which is the *pons asinorum* of gall-bladder surgery. Operations on the biliary passages include some of the most difficult in the whole field of surgery. Unless the surgeon is prepared to explore fully and deal with any of the varied and often complicated conditions which may confront him he should leave this class of case alone. It is no field for the surgical dabbler; and, further, it is one where incomplete operation makes the subsequent handling of the case a matter of great technical difficulty. As Professor Rutherford Morison has taught for so long, free exposure of the parts with accurate assessment of the full extent of the pathological process and the adoption of methods adequate for this are the two essentials. Beside these, the question of removing or of leaving the gall bladder is one of entirely secondary importance.

Mr. ARCHIBALD YOUNG (Glasgow) said: There are great names in our profession, and the bearers of these names are worthy of our respect. Their opinions, especially when given carefully and with consideration, deserve instant and adequate consideration in return. But with all this in mind we are—even the humblest of us—bound to reserve our individual rights of private judgement on any of the problems that concern us in our daily work. Mr. Rutherford Morison's name is one of the great names of our day by reason of his original work in surgery and of his vigorous and independent thought. To me, personally, his name has been, since ever I had reached the stage in my medical and surgical career to be able to appraise for myself the surgical importance of his investigations, one of a comparatively few of the great surgical names of the day in this country. I have had the opportunity of perusing, in advance, the general statement which Mr. Rutherford Morison has given of his position in respect of present-day views on gall-bladder surgery, and regarding etiology, diagnosis, and treatment of cholelithiasis. I was not unfamiliar previously with his general views on the subject, nor was I unaware of his vigorous personality or of his facility in defending any position he might find his most logical mind lead him to take up on a disputed matter. I have always admired his originality of judgement, his independence of thought, his enterprise in research, and his courage in cultivating new lines of attack upon difficult problems in surgery. If I preface what little I have to say on the subject of to-day's discussion by this most sincere tribute to the man and his work I do so as preliminary, I fear, to making for myself a profession or confession of faith which must run, in many important respects, almost directly counter to the views Mr. Rutherford Morison seems to hold to-day, much as he held them nearly thirty years ago. From what I have been able to gather of Mr. Rutherford Morison's personal

attitude to other workers and other thinkers I am very sure that any divergence of view that I may be led to express will meet with his generous consideration.

First of all as to etiology—though that does not seem to come properly within the compass of the discussion—I wish to say quite definitely that I am not prepared, even at Mr. Rutherford Morison's direction, to dismiss the theory that would trace biliary calculus formation to a bacterial source. I do not think that "there is sufficient evidence against this view to condemn it." Not that I think the theory of bacterial origin meets all the facts, nor that it can ever be taken as adequate in itself. But, after all, in very few conditions, admittedly caused or at least contributed to by bacteria, does one pretend that other factors do not also come in. Indeed, there are almost always contributory agents which play a varying important part in etiology. But Mr. Rutherford Morison must surely be prepared to advance some sort of more or less definite substitute before he can expect us, at his fiat, to give up the bacterial theory, even in favour of his rather indefinite suggestion of a purely chemical cause. The predisposing causes which he cites are as consistent with a bacteriological cause as with any other. Indeed, in my view, they greatly add to the probability of it ultimately proving to be the correct theory.

The diagnosis of gall stones is not by any means the easy or plane-sailing affair that I confess my perusal of Mr. Rutherford Morison's statement would lead me to think he wishes us to accept. Most surgeons, I imagine, must have realized long ago how difficult it is in many cases to arrive at a diagnosis in respect of at least three conditions, which take origin and produce symptoms in the segment of the abdomen in which are situated gall bladder, pylorus, first part of duodenum, and head of pancreas—I refer more particularly to purely gall-bladder conditions, pyloro-duodenal ulcer or pyloric cancer, and pancreatic lesions. Indeed, the upper right quadrant of the abdomen furnishes material for many clinical problems, and not few are the conundrums which present themselves from that area, only to be solved when the surgeon opens the abdomen—if even then. Pain in that area, or even—and perhaps all the more if—referred to the shoulder, or to some other site related to the same or contiguous spinal segment, may equally well be the result of several different lesions, of which gall stones and cholecystitis form only one, and perhaps not the most frequent. Then there is the possibility of confusion between biliary colic and the pain associated with appendix lesions—not at all an infrequent difficulty. Of course, such initial difficulty may not greatly matter where the condition is not acute and where time remains to consider the case from various angles. But it is precisely in the urgent and critical cases that this possible difficulty perhaps most often emerges, and pain in these is often enough a very unreliable guide from the point of view of localization of the lesion causing it. Over and over again I have been asked to see a patient supposed to be suffering from appendicitis, only to form a quite different diagnosis: the condition either obviously one of gall stones, with very acute cholecystitis, or another lesion of an acute inflammatory kind, related to the upper right abdominal quadrant. But this must be a familiar problem to most surgeons of experience. For these and other reasons I would urge that what we most want is not to be told about the diagnosis of gall stones in a merely general way but to have worked out for ourselves and others something like a coherent and consistent differential diagnosis.

Treatment of gall stones, of the cholecystitis associated with them, and of related conditions such as pancreatitis, is, however, probably the more important part of to-day's theme. I can touch on only a few aspects. First of all, as to the mode of approach to the gall bladder and ducts. I have been accustomed to employ the upper right rectus incision—the Robson method, as I know it. I am aware that Meynihan and many others have advocated oblique or transverse hypochochlear incisions, and Mr. Rutherford Morison's incision has its supporters. We know how vigorously he is prepared to defend it himself. I understand that the Morison route of approach is advocated for two main reasons—(1) as giving the most free and adequate access to the gall bladder and ducts. (2) as giving, if required, an efficient route for drainage. Regarding the former, I can only say that I have found the Robson route give as free access as one can want, and one can enlarge the incision in a downward direction as much as may be required. Robson suggested its prolongation upwards as required. If properly made, it

takes one down, in nearly every case, directly upon the fundus of the gall bladder, and from thence the region can be readily explored as may be proper. I am at one with Mr. Rutherford Morison as to the advisability of making a full and free incision. I have always been against any operative procedure that involves working in the dark. A generously made wound, no matter how large, cleanly cut, and not stretched and confused, will heal with far less risk of trouble, at the time or after, than a small wound which has required to be stretched and drawn upon to admit of the operative procedures being carried out at all. Further, it will have permitted of the most satisfactory carrying out of the crucial purposes of the operation. Regarding the second claim in respect of drainage, I am fully persuaded that I can procure as adequate drainage by the Robson route as by any other, provided that the patient is nursed in the Fowler—or, rather, the sitting-up—position. And when I say "sitting-up" I actually mean what I say. Often enough I have found it a little difficult to bring this home to new nurses or new house-surgeons. I have found by experience that this position is most comfortably secured by pillows alone. The patient is sat right up in bed, close up against a pile of pillows, say six pillows set flat on top of each other; and a further pillow is placed close up under the patient's knees, and kept from slipping away by a strong band from each end of the pillow tied securely to the top of the bedstead. The idea that by sloping the pillows the patient can be made more comfortable is a mistaken one, and has only the effect of causing pillows and patient to slide constantly from the proper position. In this bolt-upright position, the patient is comfortable, is seldom sick after the anaesthetic, and is assured, even with the Robson incision, of adequate free drainage. A final recommendation, in my opinion, of the Robson incision is the fact that hernia afterwards—no matter how much sepsis may have to be dealt with, or how long the wound may have to be drained—does not occur. I always, of course, close the wound in layers, leaving only the part where the drainage tube or the packing emerges. The only case in my experience where hernia followed upon one of my gall-bladder operations was the only one in which I was tempted to depart from the Robson incision in favour of an oblique transverse one. That may be, of course, only my luck, but the fact is there. Next, as to the type of operation to be performed, it seems to me that this is impossible of settlement on any general principle except this, that each case must be judged on its merits. In only a few cases is it possible to say beforehand, "This is a case for drainage of the gall bladder," or "This is a case for excision of the gall bladder." My own statistics show that the period of convalescence is considerably shorter after cholecystectomy than after cholecystostomy. One is not surprised at this, of course. The progress of events after the two operations is altogether different, and rapidity of closure of the wound must be different in each. It is possible to say, too, that the death rate after cholecystectomy is greatly less than after cholecystostomy. But that is not to say that cholecystectomy is safer as an operation in all gall-bladder conditions than is cholecystostomy. Indeed, it is not so. It merely implies that, in suitable cases, cholecystectomy is a safe operation in the hands of a competent surgeon. If death is more frequent after cholecystostomy—as my own and, I fancy, other statistics have shown—it is because that operation, while being the only correct line of treatment in certain grave cases for which cholecystectomy could never have been employed, has yet failed to save the patient. It has so failed, not because of defect in the operation as such, but because the patient has been so profoundly poisoned or so greatly weakened beforehand that no operative treatment could avail.

In conclusion, may I give certain facts and figures from my own records of operations on the gall bladder and ducts? They do not cover anything like the total number of gall-bladder operations that I have carried out, of very many of which, especially during the period of my earlier years of junior work, I have, unfortunately, no record. The figures are of cases of which I possess the records, in most cases fairly completely and carefully kept. The cases recorded number, in all, 91—78 females and 13 males. Cholecystostomy was performed, alone, in 50 of the 91 (Group 1); cholecystectomy, alone, in 25 of the 91 (Group 2); partial cholecystectomy, alone, in 7 of the 91 (Group 3); cholecystostomy plus choledochostomy in 4 of the 91 (Group 4); and cholecystectomy plus choledochostomy in 5 of the 91 (Group 5). In

Group 1 (cholecystostomies), death took place in 5 out of 50. In Group 2 (cholecystectomies), death did not occur at all—all the 25 cases in the group recovered. In Group 3 (partial cholecystectomies), there was no death—all 7 patients recovered. In Group 4 (cholecystostomies, in which choledochostomy was done at the same time), death took place in 2 out of 4 cases. In Group 5 (cholecystectomies combined with choledochostomy), death occurred in 1 case out of 5. Or, putting these figures another way, 8 deaths occurred in the 91 cases—a percentage of 8.8. Of Group 1, 5 out of 50 died—a percentage of 10. Group 2 had no deaths—a percentage of 0. Group 3 had no deaths—a percentage of 0. Group 4 had 2 deaths out of 4—a percentage of 50. Group 5 had 1 death out of 5—a percentage of 20. When one comes to consider, however, what were the conditions present in the fatal cases it becomes evident, I think, that in few—indeed, in hardly any—could the type of operation adopted be regarded as, in itself, determining the fatal issue. In other words, in almost all, death resulted not because of any inherent defect in the type of operation, or in its execution, but from the intrinsic weakness of the patient or the already advanced stage of the disease. The causes of death in the 8 fatal cases were as given in the following list: (1) Profound toxæmia—death on twelfth day; (2) primary carcinoma of liver, originating in bile-duct epithelium (*post mortem*); (3) pneumonia—death on eleventh day; (4) primary cancer of common duct—death on sixth day (*post mortem*); (5) toxæmia, acetonaemia—death on second day; never rallied from anaesthetic; (6) carcinoma of pancreas—death on second day (*post mortem*); (7) haemorrhagic pancreatitis—death on fourth day; (8) general exhaustion, following prolonged suppurative cholecystitis untreated till late—death on fourth day after operation. Amongst the cases which recovered were many difficult and grave enough, requiring operative procedures testing not merely the endurance and physical powers of the patient but also the courage of the operator. In one case transnodal choledochotomy was necessary; in many the appendix was removed at the same operation; in two cases gastro-jejunostomy was combined with cholecystostomy; in another case cholecystectomy was combined with appendectomy and colopexy, according to Waugh. All these cases did well. It seems clear that it is something quite apart from the mere severity of the operation chosen, as such, that determines the issue, successful or the reverse.

Mr. R. H. PARRY (Glasgow) said: I have been reviewing my work on the biliary tract, on the completion of thirty years' work in the Victoria Infirmary, and I have been much impressed by the influence of delay both on the extent and character of the pathological changes in it. Even in the last five years of this period the number of cases of suppurating gall bladder and of large stones in the common duct were too numerous, and would suggest a lack of lead on the part of physicians and surgeons on the value of early interference. Draining of the gall bladder or excision of it must depend on the interpretation of the pathological changes as influencing the function of the gall bladder and of the possibility of infection spreading from it by the lymphatics to the contiguous structures. In a definite attack of gall stones we should emphasize the importance of early operative interference as we do in the first attack of appendicitis. I believe that if this were to become the rule, and were the same subject to be discussed at the next meeting of the British Medical Association in Glasgow, it would be found that the treatment had been very much simplified. It should also be more definitely recognized that the presence of large gall stones in the common duct, whether primarily formed there or discharged from the gall bladder, and the disturbance which attends their removal may lead to serious changes in the function of the duct and of the valve at its junction with the duodenum. Regurgitation of the contents of the duodenum into the common duct has been shown to take place in some cases previously operated on but which called for exploration and drainage of the dilated common duct for the recurrence of pain and jaundice. Any measure directed to the protection of the common duct and the maintenance of its full functions is of paramount interest and importance.

Mr. T. S. NOVIS (Bombay), in speaking of the infection of the gall bladder with the bacillus of enteric fever, narrated his experiences of a case in which a patient came to him with a discharging sinus connected with the gall bladder, the discharge from which contained typhoid bacilli.

Mr. R. D. MOTHERSOLE (Bolton) had had experience of a case in which drainage of the gall bladder had been performed by Robson, and the patient had been free from symptoms for ten years. Symptoms of cholelithiasis again appeared, and another operation (twelve years after the first) was performed; on that occasion the gall bladder was shrunken, and in the common duct there was a huge stone three by two inches. Another point of interest in the case was that the drainage tube at the second operation came out too soon, and after its replacement duodenal contents began to escape through it.

Mr. R. M. HANFIELD-JONES (London) said: The difficulties of diagnosis of gall stones having been alluded to this morning, and the increasing efficiency of x-ray methods by Mr. Wilkie, leads me to present to you a method which will render a radiological diagnosis correct in a very large majority of cases. I refer to the method of producing pneumoperitoneum. Some of those present will remember the very striking demonstration of such a method by Professor Carelli at the Royal Society of Medicine last winter. Briefly, oxygen or CO₂, or preferably a mixture of the two in equal quantities, is injected through a very fine needle into the peritoneal cavity. The injection must be done slowly and at no great pressure—a mercury blow-off prevents more than 10 mm. of Hg, and a mercury manometer in the apparatus will give the intra-peritoneal pressure. The dangers are—first, that the needle may penetrate the intestinal canal; this can be judged by a fall in the manometer reading on entering the peritoneal cavity and a rise if it enters the intestine; secondly, when the injection is complete (namely, about 500 c.cm.) the patient must not move himself at all during the taking of the plates; and thirdly, the gas must be removed before moving the patient from the table, by introducing a large bore cannula into the peritoneum. With regard to treatment, without going into the vexed question of cholecystectomy versus cholecystostomy, I would say one word about the technique of the former. I readily endorse Mr. Young's remarks on the desirability of starting the dissection at the fundus and not at the duct. The upholders of the latter procedure must take it for granted that in all cholecystectomies there is no induration of and around the cystic duct. As a dissecting-room exercise in a normal subject, the duct and artery are readily identified, but in those cases in which cholecystectomy is justified the structures of the pedicle are quite incapable of identification.

Mr. C. P. CHILDE (Portsmouth) was opposed to the employment of the transverse incision. He preferred an incision along the outer border of the rectus, and if further room were required the rectal sheath was divided and the rectus muscle mobilized. He narrated two cases where the use of the transverse incision had resulted in the formation of enormous inoperable ventral herniae.

Dr. ARTHUR T. JONES (Mountain Ash) thought that it would be of great advantage if the public could appreciate the necessity for speedy operation in gall-stone disease as they had in diseases of the appendix. The great difficulty was to get the public to submit to operation, as they did not sufficiently realize that although one attack had been recovered from another was a likely occurrence.

Mr. H. S. SOUTTAR (London) said that when the gall bladder was drained every precaution must be taken to avoid typhoid infection in those handling the case, the organism being present in an active form in 4 per cent. of cases of gall stones. A median, or approximately median, incision was the only scientific one, the chief difficulty of the operation centering round the common bile duct, an almost median structure.

Mr. H. N. FLETCHER (Brighton) said that Mr. Wilkie had emphasized the bacterial origin of gall stones. It was difficult on this theory alone to account for the fact that for every male who came to operation there were eight or nine females. There must be some other factors at work, and there were two, he thought, which were specially present in the female—namely, (1) increased cholesterol content in the blood, which, for example, was often notably increased by pregnancy and by sedentary habits, and (2) biliary stasis. Apropos of the first, he had observed that a large proportion of patients who suffered from gall stones were subject to migraine attacks, an occurrence which might possibly be explained by a hypercholesterolaemia. In regard to stasis, apart from its occurring

from hyperviscid bile, there was the fact that visceroptosis, so much commoner in the female than the male, might, as Mr. Wilkie had suggested last year, cause duodenal stasis by the drag on the superior mesenteric vessels as they crossed its third part; and since Mr. Wilkie's suggestion he (Mr. Fletcher) had observed three cases of gall stones in which this was well marked and in which the proximal duodenum was much dilated. Again, there was no doubt, as Mr. Wagh had pointed out, that in some cases a proposed proximal colon could, by its pull on the peritoneum passing from the hepatic flexure to the gall bladder and cystic duct, kink the latter. Given, then, an increased cholesterol blood content plus stasis, organisms reaching the gall bladder would find exceptionally favourable conditions for their growth. Much attention had been devoted to the "digestive" symptoms in gall stones. In the past year he had kept records of twenty-three cases, and found that, in a quarter of them, pain half to one hour after food, referred to the mid-epigastrium, was a prominent symptom, and that in nearly three-quarters of them prolonged flatulent dyspepsia was present.

DISCUSSION ON THE TREATMENT OF NON-MALIGNANT AFFECTIONS OF THE COLON.

OPENING PAPERS.

I.—Sir W. ARBUTHNOT LANE, Bt., M.S., F.R.C.S.,
Consulting Surgeon to Guy's Hospital.

When I was asked to open this discussion I willingly acquiesced, though I felt the honour was greater than I was able to do justice to.

Formerly it was customary to regard the several abnormal conditions of the colon as separate entities or diseases. Personally I do not accept this situation, but consider them to be one and all the direct or indirect results of chronic intestinal stasis.

In order to substantiate the accuracy and correctness of my views I must first draw your attention to the two great groups of conditions which I found in the living abdomen—namely, those cases of intestinal stagnation in which a reaction takes place and those in which it is altogether absent.

Group characterized by the Formation of Bands.

In the vigorous subject delay of the accumulated contents in the pelvic colon leads to the formation of acquired bands on the under surface of the mesentery securing the junction of the ileal and the pelvic segments of the colon. The mode of formation of this, as of all the other acquired bands which develop to hold up and secure a loaded colon, is very simple. They commence as streaks on the surface of the mesentery, starting from its base and encroaching gradually along its length. After a time they reach the wall of the intestine. The streaks soon become a distinct membrane, which at a later period may be separated from the mesentery except at its base and at its terminal extremities. This membrane tends to contract and to drag the bowel towards the iliac fossa, where it finally becomes firmly fixed. The fibres that grip the colon not only diminish its lumen by angulating it, but they also tend to reduce its calibre still further by rotating it on its long axis.

Like most of the efforts that Nature makes to help the individual to bear a useful relationship to his surroundings, this membrane serves a beneficial purpose in the first instance, tending to support the loaded bowel, and so opposing its elongation and prolapse. Later this originally useful structure tends by its contraction to obstruct the lumen of the bowel, and to place the life of the individual in serious peril. This membrane in its development is very liable to grip the ovary and Fallopian tube and to fix them immovably on the iliac fossa.

It may interfere with the function of the Fallopian tube, impeding the passage of the ovum through it and causing extrauterine foetation, or it may prevent the entry of the ovum and so render the patient sterile, on the left side. Besides securing and fixing the ovary it sooner or later surrounds it, and causes it to undergo a cystic change. Later the degenerating ovary increases in size and bursts through the surrounding membrane and forms a mobile ovarian tumour.

Gynaecologists are only too familiar with the pain which women experience in the left iliac fossa and which is so often exaggerated by the approach of the period in the struggle of the bowel to force faecal matter through the anchored and obstructed colon over the sensitive ovary gorged with blood. These conditions have been referred to fully in *Guy's Hospital Gazette* in a paper by Mr. Chapple entitled "Pain in the lower abdomen of women" (*Guy's Hospital Reports*, 1921, vol. 35, p. 164).

To this particular acquired band and to its effect on the colon I gave the name of the "first and last kink." The first because it is the earliest of the acquired membranes to develop, and the last because it is the lowest in the drainage scheme.

This development of a band controlling the lumen of the lower portion of the bowel is perhaps the most important acquired change in the whole body, since it is the primary cause of a vast amount of subsequent trouble in the gastro-intestinal tract and elsewhere. Its immediate effect in producing an obstruction at this point is to render the partially occluded colon a very common seat of cancer, while in fat subjects the bowel proximal to it is a very usual site of diverticulitis. The indirect consequence of the obstruction to the passage of faecal matter through the first and last kink is the accumulation of material in the whole length of the colon. The increased load in the obstructed bowel results in the development of precisely the same type of acquired membrane on the outer layer of peritoneum which extends from the convexity of the large bowel to the abdominal wall. It serves to fix the colon and to prevent its elongation and prolapse. It is most marked in certain positions where the consequent constriction of the lumen of the bowel may produce inflammatory or cancerous changes. The localities so affected are immediately above the iliac crests, at the splenic flexure, below the gall bladder, where an acquired band from the liver, gall bladder, duodenum, and pylorus descends to hold up and later obstruct the transverse colon, over the outer aspect of the caecum, where it has recently been called Jackson's membrane, and again on the under surface of the terminal mesentery of the small intestine, which with the end of the ileum supports the caecum, forming its internal lateral ligament. In America this particular band has been given my name and is called Lane's kink.

What I want particularly to call attention to is that these so-called separate bands are all evolutionary, and identical in origin, function, and structure, and are due to the effort of the organism to meet an abnormal loading up of the bowel because of a distal obstruction, and to enable it to perform its function to the best of its capacity and not to prolapse. As I have already pointed out the initial purpose of their existence is carried out efficiently for a time, but later the continued contraction of the newly formed membranes results in obstruction of the lumen of the bowel and in consequent disease. This is usually most marked at the ileal kink (as I call the one named after me) and at the splenic flexure.

Too much attention cannot be paid to the mechanism of these acquired membranes and to the effect they exert both immediately and secondarily upon the functioning of the large bowel. When I first described them their existence was altogether denied. Later when they were found to be only too obvious the tendency was to regard them as separate and independent structures, to argue as to whether they were congenital or inflammatory in origin, or to assert that they have no influence whatever upon the normal function of the intestine. Mr. Chapple carefully examined fifty-two newly born foetuses in *Guy's Hospital* and could find no trace of bands similar to those present in the adult. This shows that they are obviously not congenital.

No one familiar with the appearance, structure, and mode of development of the bands in the living subject could regard them as inflammatory. On the other hand, anyone who has studied the several changes which the skeleton and soft parts undergo in the varying mechanical relationship of the individual to his surroundings can have no doubt as to their evolutionary origin.

Another important development which arises not infrequently in consequence of the strain exerted by the loaded caecum is what I called "the controlling appendix." It is one of very great pathological and clinical importance. This, like the ileal kink, has now been pretty generally accepted by surgeons. Instead of developing a membrane on the under surface of the

mesentery of the terminal ileum the appendix is employed in the novel function of a ligament. It becomes attached by acquired adhesions to the under surface of the mesentery and therefore it lies behind the end of the ileum. By the gradual contraction of the acquired adhesions it is rendered progressively more tight. Its situation is such that when the ileum and caecum drop into the pelvis the ileum is kinked abruptly over the anchored appendix, and like an uninflated tyre hung over a hook its lumen is more or less occluded in consequence. This controlling appendix, or the equally damaging ileal kink, is responsible for very much of the ileal stasis and infection consequent on their presence and which play such an important part in the sequence of chronic intestinal stasis. The kinking of the anchored appendix itself renders its own lumen liable to become obstructed. Consequently inflammation follows, and this attracts attention to it. The removal of such an anchored appendix is followed by great benefit to the patient.

It is in this type of static colon that cancer commonly occurs, since the factors that determine cancer and which are simply mechanical are present in a more or less marked degree. Many of the patients are robust and are regarded as healthy people by the casual observer.

Group characterized by Absence of Bands.

The other extreme type of chronic intestinal stasis is characterized by a complete want of effort on the part of the organism to oppose the elongation and prolapse of the large bowel, no new acquired bands or membranes being formed. The pelvic colon becomes greatly elongated, and puddling in the pelvis this long, loose bowel forms many abrupt angles and offers a great obstacle to the passage of solid material through it, since the more the individual strains to expel the bowel contents the farther is the flaccid gut driven into the lower limit of the pelvis.

While in the type first described the acquired band forming the first and last kink constitutes the chief obstacle to the emptying of the colon, in this type obstruction is due to the great elongation and prolapse of the pelvic colon, so that the mechanical conditions are perfectly distinct in the two extremes.

Following on this obstruction the proximal colon elongates to a great extent and prolapses. As far as I know the mere prolapse of the rest of the large bowel in no way affects its function except in the case of the caecum, when it may twist the end of the ileum and obstruct its effluent.* This condition of the caecum and ascending colon may be greatly benefited by plicating the bowel or by the method of anchoring advocated so strongly by Mr. George Waugh. Curiously enough the prolapse of the large bowel, or as it is technically called enteroptosis, has monopolized the attention of most operators who attempt to relieve the symptoms of the patient by fastening the bowel in position or by excising portions of the elongated transverse colon. I have seen no permanent advantage from such operations in patients on whom I have operated subsequently since such conditions are obviously secondary and not primary.

In consequence of the obstruction to the passage of the intestinal contents which results from the elongation of the pelvic colon an infection of the mucous membrane of the proximal colon takes place, producing a condition called colitis. This infection causes a spasm of the muscle wall of the colon and a consequent reduction of the lumen of the inflamed bowel, so producing a very serious mechanical obstacle to the passage of material through it. As I have previously indicated, *the mechanical conditions are perfectly dissimilar in the two extreme varieties of stasis, while between the two extremes every variety of degree and combination exists.*

In this type there is no point of constriction at which hard faeces can be definitely obstructed, and therefore no area of impact where cancer is likely to develop. For this reason cancer of the colon is not seen as a sequel in this form of stasis, though it is common in parts of the body other than the gastro-intestinal tract. I have described this fully on many occasions.

I feel that it is most important from the point of view of treatment, medical as well as surgical, that we should render ourselves perfectly familiar with the exaggerated types I have described and with the intermediate varieties.

* This was described and demonstrated in a remarkable manner by Dr. Jordan.

Operative Interference in the Type characterized by the Formation of Bands.

In the first extreme type of stasis the condition which calls for operative interference on the colon apart from cancer is the obstruction caused by acquired bands, *by far the most important of which is that which produces the first and last kink.*

The operation that I perform with great frequency is the careful separation of the bands which form this kink and the accurate apposition of the peritoneal edges should any surface be left deprived of its serous covering. Other controlling bands are sought for and if present are divided. The termination of the ileum is examined, and should a controlling appendix or na ileal kink be present these are dealt with and any raw surfaces carefully covered in by peritoneum. If the membrane forming the ileal kink is at all extensive it is important, after freeing it, to leave a drainage tube in position, for the reason that the lymphatics which are divided in the acquired membrane contain septic organisms which, if not drained, readily escape and set up a local peritonitis which may terminate fatally.

The presence of such septic organisms in the area from which the acquired membrane was removed have been demonstrated by cultures made by Dr. Nathan Mutch at the time of operation. This fact accounts for many cases of unexplained fatal peritonitis in operations on the appendix. I may say that I go through this sequence most systematically when dealing with any of their sequelae, such as gastric and duodenal ulcer, gall stones, etc.

The other but very much less frequent complication in this type in fat subjects is diverticulitis. This usually occurs in the area of bowel proximal to the last kink, or it may develop in any portion of the large bowel behind an obstruction. If still definitely non-malignant, the most simple method of dealing with this diverticular formation in fat subjects consequent on obstruction is to put the divided end of the ileum into the pelvic colon. *In this case, as in that of colectomy, the patient should be instructed to secure three evacuations daily.* By such means any regurgitation of the contents of the ileum into the colon proximal to the junction can be readily avoided.

Occasionally it is advisable to excise the diseased area and to unite the proximal bowel to the pelvic colon. This must depend on the possibility of mobilizing the bowel and upon the nature of the intestinal wall. In some rare cases colectomy offers the best results.

Another complication of this type of stasis is tuberculous ulceration of the colon, which is frequently limited to its proximal half. For this a complete colectomy may be performed, or, if the condition of the patient renders it advisable to limit the extent of the operation as much as possible, the ileum may be divided and be put into the pelvic colon and the colon excised beyond the limit of the area affected by tubercle. What procedure is adopted must vary with the conditions present at the operation.

It is the opinion of certain experts in tropical diseases that dysentery only becomes chronic in those affected by intestinal stasis, and it has been demonstrated by Mr. J. W. Jackson in an most interesting communication ("The relation of chronic intestinal stasis to chronic amoebic colitis") in the *Medical Press and Circular*, May 3rd, 1922, that chronic amoebic dysentery can be frequently cured by freeing the intestine from obstruction by band or controlling appendix.

Operative Interference in the Group characterized by Absence of Bands.

In the second type of static colon the mechanical difficulties are in the first instance the elongated pelvic colon, and in the second the obstruction consequent on the spasm of the muscular coat of the bowel produced by the inflammation of its mucous lining.

The symptoms which call for operation in this type are not due so much to the pain and constipation or diarrhoea, but to the auto-intoxication which is the result of infection of the contents of the small intestine, which produces the most serious degenerative processes in every tissue of the body and renders the subject liable to infection by other diseases such as rheumatoid arthritis, tubercle, etc.

It would seem that the simplest operative procedure would be to excise the surplus pelvic colon and to restore it to its normal length; such a measure is beneficial in certain circumstances, but in the majority of cases the best results can be

obtained by a colectomy or by dividing the ileum and putting it into the pelvic colon, taking subsequent precautions to secure the frequent evacuation of the pelvic colon which have been already indicated. Needless to say, no operation should be considered till every medical means have been taken to overcome the constipation, to allay the spasm of the muscle of the bowel by curing the colitis, and to free the ileal effluent.

I have described the operations of ileo-colostomy and of colectomy so frequently that it is unnecessary to repeat them again in detail. I would merely point out that in this type, as opposed to the other, colectomy is rendered very easy because of the prolapse and elongation of the bowel and by the absence of any retaining membranes.

A complication of the elongated large bowel which increases the obstacle to the passage of its contents is a twist. It is usually chronic, but owing to the abrupt exaggeration of the twist it may become acute and produce a volvulus. In certain cases I have excised the volvulus and in others I have performed a colectomy. The same treatment applies equally to the congenital enlargement of the colon, sometimes called megacolon.

As regards ulcerative colitis, when medical treatment has failed to bring about a cure of the condition, the only operation which has been of any real service in my experience has been a colectomy. Even after a colectomy prolonged local and systemic treatment is usually necessary for a considerable period, to get rid of the residual ulceration which so often exists in the rectum and in the portion of pelvic colon which has necessarily been left in the body.

Much the same operative treatment applies to severe cases of mucous and membranous colitis, but it is resorted to much less frequently.

Before leaving the subject of these operative procedures I would urge the importance of attempting to avoid the sequence of conditions which result from stasis and which produce so much misery and death.

Cancer is the final stage in the sequence of chronic intestinal stasis. It is the last chapter in the story of defective drainage of the large bowel, as it is in the rest of the gastro-intestinal tract. Its treatment has been excluded from consideration in this discussion.

Another effect of infection of the badly drained colon is inflammation of the appendix. On the treatment of this complication we are in general agreement.

I cannot impress on you too strongly Colonel McCarrison's experience in India. He spent nine years in the Himalayas, during which time he did a large practice, performing more than four hundred capital operations each year. During that time he never saw one case of asthenic dyspepsia, of gastric or duodenal ulcer, of appendicitis, of mucous colitis, or of cancer, all evidences of chronic intestinal stasis in their normal sequence. I have obtained precisely similar evidence from other very experienced medical men who have been engaged in practice for many years among the primitive races.

It is clearly our duty not so much to devise new operations as to attempt to prevent the diseases for which so many operations are done. This is the biggest problem before the profession at the present moment, and it is one that must be solved.

II.—GEORGE WAUGH, F.R.C.S.,

Senior Surgeon, Hampstead General Hospital, and Children's Hospital, Great Ormond Street.

The study of non-malignant diseases of the colon might easily extend over several days; this Section has allotted a few hours to it, and the individual speaker must try to content himself with a few minutes. It is not possible, therefore, within such limits to do more than indicate an outlook upon diseases of the alimentary tract which appear to depend for their origin upon non-malignant affections of the colon; to outline a mode of investigation that can be conducted by every surgeon; and to suggest conclusions that may be reached only by the patient contemplation and criticism of results that have stood the test of time.

Disease has a biological aspect that cannot be ignored in considering functional disabilities of the alimentary tract as they manifest themselves in Nature's first experiment in upright bipeds—the human race. Structure and environment must have established an equilibrium that has rendered possible the survival of man as a healthy individual, and the failure of his alimentary tract to function in such a way as to maintain a high standard of health for him can only

depend upon a maladjustment of those two factors. The interplay of these two factors has long been studied from the aspect of variations of environment, but the variations of structure representing arrested stages of embryological development of the alimentary tract have received but scant attention. The environment of man's alimentary tract differs from the environment of that of the rest of the animal world in that it is exposed to the action of gravity as a consequence of his upright position—possibly a very significant difference, and one that would require a structure specially adapted to cope with it.

The colon more than any other viscus is subject to variations of position, fixation, and structure which reveal like geological strata the successive phases of its development; and the colon, as a reservoir of solid material that increases in weight by steady accretions during each twenty-four hours, should be essentially perfect in its development to resist the strain that gravity peculiarly imposes upon it. With these malformations of the colon, primitive forms of embryology of the omentum, the biliary apparatus and the small intestine are associated in variable degree, and from their intimate anatomical relationship to the colon they must be considered in any study of structural defects.

At this stage it may be well to enumerate the structural variations that have been observed before considering their possible significance and their effect upon our concepts of the origin of disease that manifests itself in terms of functional inefficiency of the alimentary tract. The series of observations have been made upon 518 operations for the purpose of finding structural variations and restoring them to type within the limits imposed by surgical procedure. At the same time they have been studied in a series of *post-mortem* examinations in 110 children under the age of 12 years by the surgical registrar, Mr. J. F. H. Stallman, at the Hospital for Sick Children, Great Ormond Street; the cases were consecutive as far as possible, they had died from many varieties of disease, and were not in any way selected. The following structural variations were found in these 110 children: in 38 there was a complete primitive mesentery to the ascending colon; in 9 there was a long primitive mesentery to the iliac and pelvic portions of the descending colon; in 14 Lane's parieto-colic membrane was present; in 45 there was a ventral mesentery to the gall bladder; in 1 the caecum was under the liver; and in 1 the foramen of Winslow was absent. The age of the youngest child with a primitive mesentery to the ascending colon was 1 month; with a primitive mesentery to the descending colon 2 months; with Lane's parieto-colic membrane 1 month; with a ventral mesentery to the gall bladder 3 weeks; with an absence of the foramen of Winslow 2 weeks; and with an undescended caecum 3 years.

The operation group may be subdivided into 396 adults and 122 children; of these an analysis of the first 308 cases appeared in the *British Journal of Surgery* in January, 1920, leaving for record to-day the findings at 210 operations performed since December, 1919, upon 183 adults and 22 children.

In all of these cases, 210 in number, the ascending colon had retained its primitive mesentery; entirely in 177 of them so that it could be lifted out of the abdomen in its whole extent, and placed upon the towels to the left of the middle line. In the remaining 33 cases it was tied down strongly at the mid-point, with the primitive mesocolon persisting in variable degree behind the segments above and below this point. This tie-band, which passes from the antero-external aspect of the ascending colon to the parietes in the immediate neighbourhood, appears to represent the site at which disappearance of the primitive mesentery normally begins; but in these cases the process had been arrested there.

It is thus a fixed point upon which the mobile portions of the colon above and below it exert traction and modify it by drawing out the fascia of the post-lateral abdominal wall in varying degree. It is opaque, non-vascular, and on cutting through it the cellular tissue covering the quadratus lumborum muscle is revealed. It has no feature in common, therefore, with the membrane which Jackson has described in the *Annals of Surgery*, 1913, as "a transparent vascular structure like a complete new layer of peritoneum, bearing a relation to the colon that may be likened to that of the pia arachnoid to the brain, with bright red blood vessels running parallel with the long axis of the ascending colon and extending over the anterior surface of the colon from hepatic flexure to caecum." He suggests that this membrane has been overlooked frequently on account of the smallness of the incisions

used by many operators in opening the abdomen, which do not reveal the whole of the ascending colon. That criticism is not valid in this series of cases, in which the whole of the ascending colon was not only exposed but fixed along its whole length.

For nine years I have sought in vain for Jackson's membrane, persuading myself with difficulty that in two or three cases I had found something that bore some faint resemblance to the structure that he had described. But what has been present in those cases at the mid-point of the ascending colon is Lane's parieto-colic membrane, described by him in 1903, five years previous to Jackson's publication, and bearing the imprint in his description of it of his matchless mastery of anatomical detail. For the sake of historical and scientific accuracy it should be restored to its proper position in surgical literature under the title bestowed upon it by the distinguished surgeon who originally and accurately described it.

These are the chief variations in fixation, and those of position and structure must now be mentioned. In two cases the whole of the colon lay in the left iliac fossa and the left side of the pelvis, having made no attempt to rotate from its primitive embryonic position and retaining a primitive dorsal mesentery over its whole length.

In five cases the caecum lay under the liver—that is, rotation had been completed but descent had been arrested. In three of these cases the colon passed directly to the left from the caecum in the ordinary direction of the transverse colon, and with omentum arising along the whole of the horizontal loop; but in the other two the colon dropped down abruptly to the right side of the pelvis, so that with the caecum under the liver the hepatic flexure lay in the pelvis, and the ascending colon was actually upside down! From this prolapsed hepatic flexure the gut turned abruptly upwards to reach the splenic flexure, and only along the ascending limb was there an ommental attachment. In these cases of subhepatic caecum the ileum made a steep vertical ascent for two to three inches along the side of the bodies of the lumbar vertebrae to reach the caecum, and was tied down as an entirely retroperitoneal viscus over that part of its course. That the ileum compelled to pursue a vertical ascent should be devoid of mesentery is not without interest.

In two cases the colon had completed its rotation, but had dragged an opaque membrane with it over the whole of the rest of the viscera, which, with the exception of the stomach, were entirely invisible; and one had the unique experience of cutting a small hole in this membrane, which was about a quarter of an inch thick, to prove that the patients did possess a liver! They had been treated as cases of gastric ulcer, but the stomach did not reveal any abnormalities of structure.

In 123 cases the transverse colon lay below or over the sacral promontory, and the stomach was prolapsed according to variations of attachment and length of the omentum which passed between the two—that is, an excessively long loop of transverse colon with a great depth of omentum would not necessarily be associated with a prolapsed stomach, since the omentum could continue to pay out as the colon sagged without becoming sufficiently taut to exert a pull upon the stomach; while, on the other hand, a shorter loop of transverse colon, with only a short ommental attachment, would be associated with an equivalent prolapse of the stomach.

Thus a prolapsed colon can be present without a prolapsed stomach, but I have never seen a prolapsed stomach alone without a prolapsed colon during any operations upon these cases; and to treat gastropexy without reference to the colon can only be done in ignorance of the precise relationship between the two established at operation.

Associated with these variations of position and mobility of the colon is an atrophy and dilatation of its structure. In all these cases the ascending colon was atrophic and dilated, these changes being most marked in its most dependent portion. These changes were also present in addition in the transverse colon, involving its right half only in 98 cases, and involving the whole of it up to the splenic flexure in 30 cases. This is an approximate classification that showed that a tendency existed for these changes to spread from the right to the left of the colon to an extent that varied with the chronicity of the case. In the descending colon a patchy distribution of these changes was confined to those parts of the descending colon that were excessively mobile from persistence of primitive mesenteries. Between the splenic flexure and the brim of the pelvis it was rare to find them when the gut was normally fixed, while the pelvic loop

appeared to be more and more ballooned in proportion to the length of the primitive mesentery that supported it.

In 5 cases the whole of the colon was atrophic and dilated from caecum to rectum; it could be lifted entirely out of the abdominal cavity, including the splenic flexure; and, although they were all under the age of 30 years and had drifted from bad to worse under all forms of treatment, I did not consider that surgery could step in at that stage with advantage, or with any hope of undoing the irreparable damage that had converted their healthy adolescence into a premature middle age.

Of associated structural variations a stout mesentery passing from the ventral aspect of the gall bladder and tying it down across the duodenum to the colon in the region of the hepatic flexure was present in 76 cases.

In 7 cases the foramen of Winslow was absent and was represented by a dimple in the posterior layer of the gastro-hepatic omentum, which then passed abruptly backwards to the posterior abdominal wall.

In 18 cases a stout membrane passed from the hinder edge of the under surface of the liver along its whole length, both in the greater and lesser peritoneal sacs to the viscera in immediate relationship with it, more especially the pancreas, the pylorus, the duodenum, the upper and outer aspect of the ascending colon, and the right kidney. At no point except at the extreme tip of the right lobe was it possible to pass between the liver and the diaphragm. Through these membranes—the one from the ventral aspect of the gall bladder and the one from the under edge of the liver—the mass momentum of the liver pounding up and down during respiration is transmitted to the viscera to which they are abnormally attached; and these are not normally subjected to such a stimulus. It is not unthinkable that such a stimulus may have some effect upon the blood supply, the nerve supply, or even the structure of the viscera implicated.

Time permits of no more than this hurried summary of gross structural variations present in patients suffering from gross functional inefficiency of their alimentary tract. The clinical features of these cases have already been described in full detail in the *British Journal of Surgery*, but characters peculiar to most of them in their early stages may be recalled briefly.

In their distribution they were independent of environment and no common environmental factor depending upon the differences of their social strata and personal habits could be detected as exerting any influence upon the onset of their diseases. The period of life during which functional inefficiency first manifested itself was common to most of them—between the ages of 18 and 25 years. Only a few of them had had an unhealthy childhood from diseases of the alimentary tract.

The initial symptoms were generally discomfort in the upper half of the abdomen that yielded to no remedies, and that was eventually overshadowed by pain that appeared during the course of a year. The pain also was generally experienced in the upper half of the abdomen, but was liable to variations of distribution, conduction, and character; whilst more than one kind of pain, together with a variety of discomforts, could be identified not infrequently in an individual patient.

One type is of particular interest, and was present in 97 of these patients, a type that has been described as "hunger pain," and that is peculiarly amenable to change of position from the upright to the horizontal, and is very frequently relieved by the taking of food.

Of all the alleged modes of origin of visceral pain there is one that has been translated from the realm of theory to the realm of fact, and it may be well to recall the experiments that established it beyond all dispute. Nearly thirty years ago Lennander of Upsala and Arthur Baker of London performed most of the present-day operations upon the alimentary tract under a local infiltration of the abdominal wall only with beta-cucaine and adrenaline. During the course of these operations it was clearly and scientifically shown that when tension was made upon a mesentery beyond a certain degree of tautness, pain was experienced by the patient, and no other stimulus elicited any sensation that the patient could record. Antecedence and consequence followed in an unbroken procession, establishing a law that there was a minimal strain for each mesentery which could not be exceeded without the production of pain.

The occurrence of hunger pains in patients possessing primitive mesenteries to their ascending colons, together sometimes with other embryonic bands, may well be reviewed

in the light of these experiments. Not only is that mesentery peculiarly exposed to strain by the downward-acting weight of the colon and its load, but also the strain may be taken off it by change of posture and by shifting of the load. There is a time occurrence of these pains revealed by the patients so constant that they might well be renamed "four o'clock in the afternoon" pains and "small hours of the morning" pains. So infrequently do they occur at other times in the day that patients confess they are panic-stricken by such happening, although the majority of them had never had such an experience. With regard to their habits, most of them had eaten a good breakfast and a good midday meal, so that at about 4 p.m. most of the residue of both these meals would be in the ascending colon; a good meal was eaten again, as the last meal of the day, the total residue from which would ordinarily be accumulated in the same site at about midnight.

By taking a cup of afternoon tea, a pinch of sodium bicarbonate, or a biscuit kept by the bedside for the purpose, the pain would be speedily relieved. It is known that by any act of ingestion into the stomach a gastro-colic reflex is initiated whereby the load from the ascending colon may be passed on into a more distal segment of gut; this presumably happened in these patients, and afforded them the expected relief.

Change of posture was temporarily effective, if they could get their heels higher than their head; but the relief was purely temporary, and in some cases no relief at all was afforded when the ascending colon hung so far over the pelvic brim that it could no longer ride up on assuming such a position.

In the light of these facts it seems a reasonable inference that this particular pain does originate from the downward drag of the loaded ascending colon upon its own mesentery, and that the relief from the pain afforded by fixing the colon cannot be regarded as a pure coincidence.

None of these cases had duodenal ulcers discoverable by operation; 46 of them had already had the appendix removed—the purely epigrammatic solace for failing to find the ulcer or gall stones so confidently diagnosed in these cases—without relief to their symptoms; and the precise diagnosis of duodenal ulcers, together with those of gall stones and gastric ulcers, may well be grouped together as unscientific conjectures that are sometimes right.

By the time that pain had become an established feature of these cases general malnutrition, as shown by an average loss of 1 st. to 3 st. in weight, preceded on its course unchecked by many remedial measures such that changes of environment could afford; and the buoyant adolescent of 18 had now become the weedy dyspeptic adult of 25.

Such are the common features of the early stages of failure in function of the alimentary tract in these individuals whose gross structural anomalies have been demonstrated upon the open abdomen. Further, it may be noted that they were not cases of primary constipation or of general visceroposis. In only 28 of them had constipation preceded the other troubles, whilst its appearance was delayed in most of them until four or five years of suffering had been experienced.

The position of the viscera and their range of excursion were noted by the only precise method at our disposal—that is, when the abdomen had been opened with the patient in the horizontal position on the operating table. All of them had a prolapsed ascending colon, some of them had a partially prolapsed transverse colon and stomach, 95 of them had a prolapsed right kidney; but none of them had a prolapsed right kidney, pancreas, descending colon, or left kidney. To liver, spleen, pancreas, descending colon, or left kidney. To be quite precise, the left kidney was mobile and prolapsed in three of them.

A description of the individual variations in symptoms added on to the common symptomatology cannot be entered upon now, and it must be mentioned merely in passing that several of them had had renal crises with healthy kidneys and normal renal secretion, and had been suspected of harbouring renal calculi; others of them had had biliary crises with healthy gall bladders and healthy contents, and had been treated for gall stones.

Thirty-two of them had undergone "cures" for colitis, in some instances lasting as long as five years, whilst under the many diagnoses of duodenal ulcer, gastric ulcer, gastroptosis, gastralgia, gastric neurosis, neurasthenia, and psychasthenia the most ingonious changes of environment had failed to stay the course of their sufferings.

Of surgical measures that had proved ineffective before these patients came under my care, from 46 the appendix had

been removed, in 5 the gall bladder had been drained, in 9 a gastro-jejunostomy had been performed, and in 1 of them a gastroplication.

To summarize briefly the operative procedures performed upon these 210 cases: In all of them the ascending colon was fixed to the posterior abdominal wall in what approximated to the normal position. As additional measures the atrophic right half of the transverso colon was fixed by Coffey's method in 128 of them; the ventral mesentery of the gall bladder was cut away clean up to the free edge of the gastro-hepatic omentum in 76 of them; the gastro-jejunostomy union was resected and the stomach and jejunum restored to their normal isolation in 6 of them; gall stones incidentally found were removed and the gall bladder drained in 3 of them; and the gall bladder excised from 1 of them who had a permanent biliary fistula from a previous drainage operation done elsewhere.

The appendix, which was still present in 164 of them, was removed and was obviously diseased in 4 cases; whilst in the remainder it was strikingly small and healthy in appearance. In 2 cases ileal kinks were cut away. With regard to the "first and last kink" I was unable to differentiate it from the fascia covering the iliacus and obturator muscles on the left side, drawn out by a pendulous loop of iliac and pelvic colon that had retained its primitive mesentery. This condition was only present in 35 cases. Masses of adhesions from previous operations had frequently to be waded through before the final operation of reconstruction could be begun. There were four deaths from the operation in the total series of 518 cases; two of them have already been recorded in the original paper, while the third occurred in the series of cases now under review from post-operative pneumonia followed by an empyema that proved fatal on the seventeenth day after operation. The fourth—the only one that occurred in a child—was from diphtheria, for which tracheotomy had to be performed within thirty-six hours of the operation, but the patient died a few days later. The operative death rate is thus only a fraction of 1 per cent., and the operation of reconstruction of the alimentary tract may at least claim to range itself amongst the safest of surgical procedures.

Of late complications, in 8 cases attacks of intestinal obstruction from adhesions came under my notice during the last eleven years. In 6 of them a knuckle of small intestine was adherent to the under aspect of the laparotomy scar and in 2 of them the omentum was adherent to the floor of the pelvis. Thus the formation of adhesions as shown by their distribution was not peculiar to an operation for readjustment of the position of the colon and they appear to represent a very average risk of any interval abdominal operation.

The number of patients who had extensive peritoneal adhesions from previous operations before coming into my hands were 58. These adhesions were carefully undone before proceeding with the operation of reconstruction, and in estimating end-results have necessarily to be taken into account.

The results can only be presented to-day roughly in three groups—failures, improvements, and apparent cures. Twenty patients write to me that they are no better (in the space on the form that they are asked to fill in under the heading "Present condition," one of them writes laconically the single word "Rotten"), but they add that they are no worse!

There is an intermediate group who have lost a great many of their old troubles, and, whilst they are not entirely free from all symptoms, they say that their health has been materially improved, and are gratified by what has been achieved for them.

Whilst finally, as a set-off to these two groups, there are 98 who declare, after periods varying from eight to five years since the operation, that they are enjoying a degree of health that they had never previously experienced, and that they regard themselves as perfectly well.

Many enumerate in detail how they have passed from a life centered around the search for new remedies for their intestinal troubles to one of active participation in sport and work. The rate of improvement in their records is most variable and interesting: in some, a long climb uphill to a reasonable standard of health was in front of them, in others an abrupt and dramatic change for the better has occurred.

Two patients, both under 30 years of age at the time of operation, performed seven years and six years ago respectively; had been practically bedridden for one year beforehand. During the subsequent year they made a slow and steady improvement, at the end of which time they have entered upon a practically unbroken spell of buoyant health and have increased their weight by an average of 2½ st. apiece.

As a contrast, a young man of the severe hunger pain type, of two years' duration, estimates one year later that his progress is "pretty fair," adding incidentally that his weight in that time had gone up from 10 st. 1 lb to 12 st. 7 lb.

Such, then, is the brief picture of gross structural variations in the alimentary tract of 210 cases; of the clinical aspect of the functional disabilities of the alimentary tract from which they suffered; of the method, details, and risks of an operation of reconstruction undertaken to restore them to type (essentially conservative and physiological in its principles and not substituting an alternative pathological condition for the original one); and of the end-results that have been achieved.

The general principles involved in these studies must once more be referred to in conclusion. The whole philosophy and practice of medicine from time immemorial has regarded environmental factors as the cause of early stages of functional disability in the alimentary tract, and the question of whether pre-existing structural defects that have been present from birth have at last revealed their presence by an inevitable failure of function has seldom, if ever, been raised.

As the logical outcome of such a premise, changes in environment have formed the basis of treatment, which comprises elaborate changes in the proportion of the proteid carbohydrate and fat elements of diet, and the administration of animal, vegetable, and mineral substances from a swollen pharmacopoeia.

With the failure of these measures to afford relief, fresh concepts of functional inefficiency in the endocrine system, the autonomic nervous system, the central nervous system, and finally the psychic nervous system, have been evoked to explain the slow progressive breakdown of normal function in the alimentary tract, in spite of the environmental readjustments to which it has been exposed. That lesions of one or all of these systems should have caused patchy distribution of the deformities already enumerated seems unlikely; but that the structural deformities primarily present in such a case may have been responsible for a secondary involvement of these systems is not unthinkable, with the ultimate establishment of a vicious circle.

Now the perfectly developed alimentary tract can only have been one with a structure of enormous resistance to hostile factors in environment to have permitted the human race ever to survive. The incredibly filthy habits of the cave man with his uncooked, unanalysed, and unwashed food, his unwashed hands, his unclipped nails, his louse-infected body, and his ignorance of sanitation, would long ago have swept the human race from the face of the earth unless many of them had been adapted structurally to resist such an environment successfully.

This environment is faithfully reproduced in the homes and habits of slum dwellers of to-day. Yet from these same slums you may hale forth eupeptics, affording a contrast between the rude health they enjoy and their violation of all laws of sanitation and dietetics, that is an astounding testimony of the innocuousness to them of their environment.

The dyspeptics are there too, and in large numbers; but so also the eupeptics and dyspeptics abound in the teeming multitude of suburban dwellers and amongst the ranks of the wealthy and leisured classes. Than the last class perhaps none are brought up more strictly from childhood under the guidance of distinguished leaders of medical thought in the laws of dietetics—that is, amidst an environment for the alimentary tract in which function should be performed most efficiently and with the least exposure to the menace of hostile factors.

Nevertheless, in these three large social subdivisions of the human race whose environments are characterized by the most divergent elements, eupeptics and dyspeptics abound with a constancy both inexplicable and bewildering if variations in environment are to be regarded as the sole determinants of efficient or inefficient functioning of the alimentary tract.

This theory of the sole influence of environment clearly breaks down in the presence of such widely distributed phenomena of alimentary tracts defying the foulest environment with success, and succumbing ignominiously when sheltered by the fairest. Some other factor that determines so erratic a distribution of these ills must be taken into account, and I venture to suggest that that factor is represented by gross structural anomalies of the alimentary tract which are present from birth. For them no environment that is suitable has as yet been found; whilst in their absence it seems biologically true that no environment is unsuitable.

The exposure of the alimentary tract to the influence of gravity as the result of man's upright position has imposed upon it a strain unique in the animal world. Solid ingested material has to move against a resistance that can no longer be merely expressed in terms of the coefficient of friction between itself and the mucous membrane of the alimentary tract, since a vertical uphill path has to be traversed in part of its course against the tendency of its own weight to drop downwards. This tendency, moreover, is still active during the resting phase of the solid material, so that its full weight has to be supported with the minimum expenditure of energy and the force of expansion exerted upon the wall of the segment of gut that contains it appropriately overcome.

A structure efficient on the physical side for the purposes is likely to have been evolved and probably finds its best expression in a fixed ascending colon that has rotated to its appropriate position on the right side of the body. In the absence of such fixation the gut and its load must slip downwards, whilst the expansile force of the load will exert its maximum effort unchecked by the unsupported walls of the gut.

That atony and atrophy of its fatigued musculature should ensue over the areas where the strain is greatest is no matter for surprise in accordance with the physiological law of the effect of continuous stimulation. Not only would hypertrophy be utterly impossible under these conditions, but its occurrence would be so inexplicable as to need revision of these laws.

The involvement of the nerve terminals of the mesentery, at least to the extent of the production of pain, and the alteration of the venous exit of blood from the horizontal to the vertical direction through the vessels of the ascending colon, are additional factors probably in producing this condition and cannot be ignored; although the precise amount of their influence cannot as yet be demonstrated experimentally.

The effect of rest cures upon these patients prior to operation affords a study of great interest, since the common feature of all their cures was the removal of the patient from the position of the biped to that of the quadruped by permanent maintenance in the horizontal position. With very few exceptions all of them to the number of forty-six experienced great relief, and when the relief passed off on resumption of their ordinary life as a biped their faith was only slightly shaken in its efficacy of finally affording them a permanent cure.

A series of cures ultimately shattered their faith that by such means their viscera would be made to stay permanently in their normal positions, although such a promise could only have been made to them with a total ignorance of the structural lesions that were actually present in their alimentary tracts.

Ultimately 19 of them were persuaded to undergo rest cures in the Trendelenburg position—a mode of treatment whose pharmacological action can hardly be stated, but whose mechanical effect can be appraised with accuracy. Of necessity this method also failed and permanent relief was only obtained after a reconstruction operation upon the alimentary tract had been performed. But the flotsam and jetsam of spas, health resorts, and systems of cures are not cases at a stage when surgical measures as a last resource should be undertaken for them.

Such final chapters of pathology should never have been written, and they can merely be used to point the moral that the prevention of their occurrence by successful treatment in the earlier stages is the direction in which progress must travel. That I believe is the essence of the teaching of the distinguished opener of this discussion.

I have never performed a total colectomy or a short-circuiting operation and only two hemi-colectomies for non-malignant diseases of the colon; but to have done so upon the many cases upon whom I have refused to operate at all could not have added to their miseries, and I realize that I have abandoned them to the hopeless quest for relief by some other means.

By way of recompense for such an omission the boundless measure of thanks from those enumerated in this series, to whom reconstruction operations have restored so great an amount of health, should be gratefully offered as tribute to the pioneer, Sir Arbuthnot Lane, who has guided our thoughts in the direction of a search for procedures that may prevent the total and final débâcle of all alimentary tract functions.

III.—Sir HENRY M. W. GRAY, K.B.E., F.R.C.S. EDIN., Surgeon, Aberdeen Royal Infirmary.

In contributing to this discussion I propose to deal chiefly with developmental pericolic adhesions, but in a very different way from Sir Arbuthnot Lane, as I disagree with him entirely with regard to their etiology. For many years they have been to me the most interesting of the non-malignant affections of the colon. Their developmental origin became evident to me very soon after I began to study them systematically. Their effects are still, in the opinion of many surgeons, problematical. The question of their treatment must therefore be considered to be very much in the melting-pot. I shall discuss only those found on the right side of the abdomen. They are the most frequent and the most frequently assertive in causing interference with normal health. It seems reasonably justifiable to believe that, so far as the functions of the colon as a whole are concerned, the first part, consisting of the caecum and ascending colon, is the most important, in that it makes the pace, so to speak, for the rest. If it is out of gear the rest of the colon will not work properly. Therefore, if abnormalities of this first part are found, it seems to me that it is one's duty to try to decide whether these abnormalities are actually causing or are likely to cause interference with health, and if so to settle what is the best way of correcting them. I believe that in most cases this will be obtained by rearranging the parts in conformance with Nature's intention. Therefore it is essential to know the real process of development of these abnormalities. Abnormalities are so frequent that this becomes an important question if patients are not to be subjected to repeated operations, or if, in other words, they are to be restored to the most perfect attainable health by one operation.

One must not disregard other congenital adhesions which may affect the splenic and sigmoid flexures, sometimes in a very deleterious manner. Sir W. Arbuthnot Lane has devoted much attention to these adhesions, and he deserves very great credit for pointing out so well the evil effects of chronic intestinal stasis; but I venture to say, with all deference, that his theory that such adhesions are due to chronic constipation does not by any means sustain the acceptance which it obtained when he first enunciated it. He placed the cart before the horse. As I stated years ago, these adhesions may lead to constipation and may be aggravated by the inflammation which sometimes results from such constipation. According to Lane, the various abdominal bands of adhesions found at different parts are due to "crystallization of the lines of strain." This expression is difficult to comprehend, especially when one finds such bands already very evident in the foetus and in young children, whose structures cannot have been subjected to any but the slightest strain, if indeed to any at all. The effect of strain on other intra-abdominal adhesions is usually to stretch them and promote their absorption. Such an independent observer, as Bryant of Boston found such bands present in some part of the abdomen in all the male foetuses he examined and in 87.5 per cent. of the female foetuses. It is interesting to hear that Mr. Chapple, a vigorous supporter of Sir Arbuthnot Lane, could find "no trace of bands similar to those present in the adult" in any of the foetuses he examined. From my experience of abdominal surgery in young children, I cannot believe that Bryant is very far wrong in his observations.

Notless sacrifice of the colon has not found general permanent favour in the minds of the profession, and I feel that the results of extensive colectomy in such cases have not improved the condition of my patients to a degree at all commensurate with the severity of the procedure. In only two out of eleven cases of removal of the major part of the colon in my private practice have the patients expressed themselves as being satisfied with the result of the operation.

The more one studies the interior of the abdomen and the attachments of the viscera to the parietes the more convinced does one become that any explanation of these abnormal arrangements which is not founded on the vagaries of development is not worth considering. One is, further, so much impressed with the frequency of their occurrence that one wonders why a description of their appearance does not find a place in the ordinary anatomy books.

Abnormalities in the mobility of the various parts of the colon are due chiefly to increase or decrease in the fusion of, or in the length of, the various folds of peritoneum formed in connexion with the development of this part of the bowel. Thus the mobility of the caecum and ascending colon is

chiefly dependent upon the extent and density of the fusion of the peritoneum lining the posterior aspect of the corresponding part of the mesocolon and of the colon itself with that lining the posterior abdominal wall. The height, fixity, and to a great extent the angulation of the hepatic and splenic flexures depend on the length of the right and left borders of the omentum which tack these flexures to the abdominal wall or adjacent viscera. Interference with motility as well as mobility may be caused by these slings and by the other developmental adhesions whose mode of formation I shall now discuss. These membranes are of little use as support to the bowel, although they may exert a deleterious kinking action. I shall deal chiefly with the so-called Jackson's membrane, but I feel that I may be excused if I include also the band known as Lane's terminal ileal membrane ("Lane's kink"), as the two are frequently associated. The reason for the frequency of the combination will, I hope, be made clear to you. I am greatly surprised to read Mr. Waugh's statement,² made in 1920, that he found Jackson's membrane only once in 180 cases. I find that it is present, to a greater or less extent, in the majority of patients in whom I open the abdomen.

As is well known, the caecum during development descends from the subhepatic region along the posterior abdominal wall to its usual situation in the iliac fossa. At first the lower end of the ileum and the ascending colon are provided with a long mesentery and mesocolon. During and after descent of the caecum these structures become blended or fused with the peritoneum lining the posterior abdominal wall so that the lower part of the ileal mesentery becomes quite short and the mesocolon as a separate entity disappears, while the colon itself frequently becomes "sessile."

Sometimes the caecum does not descend, and in these cases one may find that the lower end of the mesentery and the ileum have become plastered on to the posterior abdominal wall in the same way and in the same position as the mesocolon and ascending colon normally are arranged. If delay in descent of the caecum occurs, this adhesion of the mesentery and ileum may take place, so that when, later on, the caecum descends and of course pushes the ileum in front of it, the lower part of the ileum never becomes quite free from the posterior abdominal wall—a band, Lane's terminal ileal membrane, binds it back. This "band" may be several inches broad, it may be a continuous membrane or consist of one or more tags, or any gradation between these extremes may occur according to the amount of absorption of the abnormality which takes place in Nature's struggle to reach the normal anatomical arrangement. The membrane may reach the antimesenteric aspect of the ileum or be merely attached to the mesentery according as early fusion to the posterior wall has affected the whole of the posterior aspect of the ileum and mesentery or merely the mesentery alone. (Compare the "normal" arrangement of the colon and mesocolon.) It will easily be seen that this binding of the ileum, when the membrane reaches the antimesenteric border, produces a rotation of the ileum in its long axis when it is pushed down by the caecum. When the membrane is divided the ileum almost springs into its normal position. The explanation of the fact that the ileum sometimes enters the posterior aspect of the colon becomes clear in view of what I have said. The presence of retrocaecal or retrocolic peritoneal pouches and some retroperitoneal cysts is also easily explained.

The anatomy books at my disposal are unpleasingly vague about the parts of the omentum which are important for us to consider, both with regard to their arrangement and development. The omentum extends much farther to the right than is described in them and implicates the viscera in the north-west territory of the abdomen to an extent not even hinted at. Ordinarily the omentum is depicted as stopping short of the pylorus, whereas there is no distinct margin at its attachment, on the right, to the stomach or transverse colon. It blends with a membrane, often very distinct, which stretches from the transverse colon up over the pylorus and duodenum to the lesser omentum and gall bladder. To the right of the foramen of Winslow this membrane passes up frequently to the under surface of the liver and in practically all cases to the posterior abdominal wall just below that viscus.

The chief cause of non-descent of the caecum appears to be abnormal entanglement thereof by this right margin of the omentum, which becomes much more evident in these cases. If the caecum ultimately overcomes this obstruction to its descent the affected part of the omentum becomes drawn out into Jackson's membrane. This usually filmy structure,

with its long linear vessels and occasional little islands of fat, has a very variable attachment above and externally, but can be traced below and internally usually to the anterior longitudinal band, where it ends in the same manner as the main part of the omentum does on the transverse colon. Curiously in the adult it does not often reach the caecum. A well-marked Jackson's membrane can always be shown to be directly continuous with the ordinary omentum. As the transverse colon is approached more and more fat is found in this membrane, so that there is no real line of demarcation. While the upper end of Jackson's membrane is usually attached more or less broadly, and sometimes quite low down, to the posterior abdominal wall below the liver, or may extend a little on to the adjacent under surface of the liver, I have seen several cases where the membrane arose chiefly from the under surface of the liver external to the gall bladder, and from the adjacent anterior abdominal wall as well. It is not to be wondered at that this membrane should vary in obliquity and in length and thickness at different parts, so much so that quite substantial bands may be present which may be so short as to interfere with the movements of the colon—that is, at any part it may be a direct cause of stasis because of the kinking which is caused. There is often quite a thick part attached to near the middle of the ascending colon. As already indicated, chronic irritation from absorption of toxic products may lead to further thickening of such pericolic membranes, and thus a vicious circle is produced. In this connexion I cannot understand why Sir Arbuthnot Lane should assume that a reaction from stasis should occur in one class of his cases and not in the other.

When the descent of the caecum is retarded by omental adhesions the appendix is usually implicated by them. In my opinion this is the usual cause of a retrocaecal or retrocolic position of the appendix. The appendix, before it leaves the subhepatic region, becomes caught up by the short margin of the omentum which connects it, usually near its terminal portion, to the posterior abdominal wall. Later, when the caecum descends and distends, the appendix lags behind and assumes a position posterior to the caecum and colon. In such an appendix there is usually evidence of chronic inflammation, especially near the tip, which is often hook-shaped, and the strands of Jackson's membrane in connexion with it are, as a rule, unusually fibrous in structure. When it is freed the anatomical arrangements are usually found to be normal, both as regards the origin of the appendix at the caecum and the appendicular vessels. It is rare to find a subhepatic appendix lying anterior to the caecum and colon. In such cases the appendix has not been caught in the coils of the omentum, although the caecum has usually descended imperfectly. It can be appreciated easily that the appendix, if it occupies a position internal to the caecum, may be caught up during the process of obliteration of the lower part of the mesentery and become more or less incorporated with the under layer of that structure. This is the real explanation, in my opinion, of Lane's "controlling appendix." Of course, in some cases the appendix becomes secondarily adherent to the under surface of the mesentery as the result of inflammation, but the two types of case can usually be easily distinguished.

I do not think it necessary to do more than mention the fact that the ascending colon and the beginning of the transverse colon sometimes become bound together by the omentum so that the arrangement is sometimes likened to the barrels of a shotgun. This abnormality is usually only part of a "complex." It is evident that all manner of variations in the ultimate anatomical arrangement of these bands and of the parts of the bowel affected by them are possible and indeed are found, but they can all be traced to deviations from the general process which I have described.

The counterpart of Jackson's membrane on the left side is usually very scanty, and does not reach far down the descending colon. Usually only a few scattered linear vessels are all the evidence of its presence. It rarely exists as a distinct membrane.

In papers published in 1912 and 1913, written in collaboration with Mr. William Anderson, I described most of the conditions drawn attention to by Mr. Waugh in his paper published in January, 1920. You will find, especially in our papers published in the *Lancet* in May, 1913, that the descriptions of the anatomical conditions and symptoms tally fairly accurately with those he has given. The European war interrupted my opportunities for observation, but I may say that both before and since the war my conclusions have inclined me to take up an attitude similar to his. In one respect my experience differs

from that of Mr. Waugh. I do not often find in my patients a true ascending mesocolon. There is practically always some evidence of attempted fusion with the posterior abdominal wall, although this may consist of only filmy, loose connective tissue. In my cases, also, there is always a more or less definite Jackson's membrane. This association indicates to me that subhepatic entanglement of the caecum by omentum has taken place which has delayed the descent of the caecum until the period has passed during which intra-abdominal adhesion normally takes place. A late descent of the caecum means that faulty fusion will probably occur. It is not surprising that in many such cases the abnormal drag of the late descending caecum and ascending colon acts upon the adjacent short right part of the omentum, and results, by reason of the continuity of the structure, in formation of a potentially constricting band running over the front part of the duodenum or pylorus. Such a band may well be continuous with the congenital fold of peritoneum which fairly frequently affects the cystic duct or gall bladder to a variable extent. This connexion affords the explanation of symptoms referred to these organs in the upper part of the abdomen.

We can now consider in a rational way the probable effects of such abnormalities, and I propose to deal with these very shortly. I believe that such abnormalities are present in a large number of people who are in apparently perfect health—that only in a minority of persons are there definite symptoms which have been ascribed to their presence.

For many years I have appreciated the necessity for opening the abdomen in such a manner that the whole cavity may be explored, even although the operation may have as its primary object the treatment of symptoms which have been ascribed to disease of only one organ—for example, to a chronically inflamed appendix. One cannot always diagnose accurately the conditions which may have provoked the appendicitis or which have resulted from repeated attacks, and I feel that these often cannot be investigated thoroughly or treated efficiently through such inadequate exposure as, for instance, is afforded by the still too favoured "gridiron" incision. In justice to my patients I have become accustomed to use an extensive paracentral incision, displacing the rectus muscle outwards.

As a result of such exposure I find in the majority of my patients that "abnormalities" occur at one or more parts of the colon. A caecum and ascending colon, abnormally mobile according to ordinary anatomical descriptions, is most frequently present. This is usually accompanied by a more or less well developed Jackson's membrane, and in a considerable number of cases by Lane's terminal ileal membrane as well. The variability of the first part of the colon and its attachments forces one to a consideration of the question as to how far deviations from the normal cause abdominal symptoms or affect the general health. The same question arises in connexion with the colon as a whole. It seems that the arrangement of the colon as depicted in anatomy books is really not often found by x-ray examination. For example, the transverse colon is found in ordinary cases at a much lower level than in formalin-hardened cadavers, or in most patients who have been carefully prepared for operation. Its height varies greatly with posture and with the amount and quality of its food content. It is extraordinary how frequently well-marked kinks and convolutions in abnormal places or apparently excessive angulations at the flexures occur, without any apparent effect on the regularity and completeness with which the colon and rectum are evacuated. On the other hand, it is remarkable that an apparently normal colon, as outlined by x-ray examination, is present so often in patients who are sufferers from chronic constipation. It would appear that x-ray examination is of value in such conditions only when it reveals distinct stasis. I believe that in the average case of constipation this is due to lesions in the upper part of the gastro-intestinal tract—in the stomach, gall bladder, and appendix—probably more frequently than it is due to fault in the colon. I am glad to find that these opinions, deduced from examinations made during operation, are supported by observations made at Duff House by Dr. Spriggs and Mr. Marxer. Of course, in many cases there can be no doubt that the colon is at fault and must be dealt with. I am sure that Mr. Waugh has done good service in urging attention to the possible effects of the drag of a heavily laden mobile caecum and ascending colon. There is no doubt in my mind that this is the cause in many cases in which the symptoms

are referred to stomach, duodenum, gall bladder, or right flank, and in which these symptoms are capricious in their appearance and variable in their intensity according to the posture of the patient, his general fitness, the functioning of his bowels, etc. I think that the term "hypochoandriacal" as applied to many such patients is by no means a misnomer, and that a large number of them can be relieved by operation. The beneficial results of dividing abnormal adhesions in connexion with the organs mentioned and of fixing the caecum and ascending colon bear out the correctness of this statement. The symptoms caused directly or indirectly by such bands often mimic those of other lesions with wonderful accuracy, until closer observation reveals their capriciousness and variability, as I have just indicated. As already pointed out in 1912, and confirmed by Mr. Waugh, lesions of other organs may actually exist, being secondary to such adhesions. The possibility of such a connexion should always be investigated, and colopexy should be done if the necessary indications are present. Mr. Anderson and I further pointed out in 1912-13 that these symptoms often begin within a few years after the patient has, owing to circumstances or choice, given up the ordinary physical activities of childhood and early youth, or has, in other words, begun to lead a more sedentary or confined life. We showed that symptoms begin with loss of tone, especially of the patient's abdominal muscles, and that they vary according to his general health or tone. His alimentary canal shares in this variability of tone. Ultimately, unless he can spare odd times and cash to spend in special institutions where he can be stimulated to "carry on," he tends to become more or less a chronic invalid of the type with which Sir Arbuthnot Lane has made us familiar.

I wish now to put before you a few further remarks concerning treatment. I believe that very few cases indeed call for extensive resections of the colon as has been advocated by Lane. In my opinion this is justified only when x-rays have revealed unusual stasis in various parts of the colon and when exploration shows that the colon is unusually long, convoluted, kinked, hypertrophied, and affected by adhesions which probably interfere with its motility. In two such cases, already mentioned, I removed the ascending, transverse, and descending parts of the colon. The sigmoid colon was so long that I was able to make a new transverse and descending colon out of it. I fixed the closed proximal end of the sigmoid to the posterior abdominal wall under the liver and tacked the new splenic flexure over a broad area to the diaphragm on the outer side of the spleen. I implanted the cut end of the ileum close to the right extremity of the new transverse colon. I would here urge the importance of making the blind end of the colon, proximal to such an anastomosis, as short as possible. A long blind end is almost certain to cause trouble from dilatation, consequent stasis and dragging, even although attempts are made to get evacuation of the bowel several times a day. I may say that ten years after operation both these patients are now enjoying life, free from their old troubles, especially that of constipation. It is but just to say, however, that in one of them gastro-enterostomy was done, at the same sitting, for a well-marked duodenal ulcer.

In the more ordinary cases, however, the colon is not arranged in such a "snarl." One opens the abdomen in a patient who, for example, has complained of symptoms simulating those caused by gall stones or cholecystitis, or gastric or duodenal ulcer, or appendicitis, or such discomfort in the right flank that one suspects obstruction of the colon or renal affection. One finds no gall stones, no ulcer, no renal abnormality. There are more or less strongly marked peritoneal bands affecting one or more of these organs in the way which has been described, and there are besides a mobile, dilated, or possibly hypertrophied caecum and a similarly affected ascending colon, which, when weighed down by contents, exert a drag on these bands. In such cases the appendix is practically always thickened and congested, possibly kinked and dilated, whether it occupies a fairly normal or a retrocolic or submesenteric position. Years ago one used more to remove the appendix under these circumstances, but the results were frequently so unsatisfactory that one felt driven to do more. One then divided the peritoneal bands, but still the results were not all that could be desired, so that one proceeded farther, and, arguing from the fact that the mobile and distended caecum and ascending colon were not normal, one imitated Nature, and fixed the caecum and colon in the right iliac fossa and flank, as advocated by Wilms in 1908 and, twelve years later, by Waugh. I have done this with increasing frequency since 1912, and, I am

bound to say, with increasing satisfaction. The good results of this operation have almost waned entirely from performing excision of the caecum and ascending colon for this condition. It seems to me that this part of the colon gives rise to most trouble, and that if it is fixed it will, in the great majority of cases, regain and maintain its proper rôle in the mechanism of digestion and absorption of food. So convinced have I become of the potential evil effects of mobile caecum and ascending colon that, if I find them present when I open the abdomen for any reason, I now fix them if the condition of the patient permits the extra expenditure of time, even though no symptoms ascribable to the condition have been present. It has become to me almost as "natural" a thing to do as to remove the appendix when the abdomen has been opened for other conditions.

In performing the operation I recommend that the filmy, fibro-fatty tissue at the back of the colon be removed or pushed aside so that the colon may form really firm adhesions to the posterior abdominal wall. Care should be taken that the subhepatic flexure be not unduly constricted or kinked by the upper sutures. The caecum and colon are usually also plicated, concertina-wise, in a longitudinal direction, by catching the anterior and external longitudinal bands in the fixation sutures, so as to narrow the circumference of the bowel.

I believe that this operation should be performed much more frequently than it is at present in order to avoid disappointments in the effort to regain thoroughly good health for our patients, and also in order to prevent development of the numerous ills which are attributed to auto-intoxication from absorption. We must remember that the abnormalities which I have discussed begin to assert their evil influence insidiously at a comparatively early age, that their effects often become aggravated after any serious illness, and that their presence can be fairly accurately diagnosed by a just consideration of the local symptoms, especially if the patient shows the narrow abdomen and rather broad pelvis which may be looked upon as being frequent concomitants.

IV.—HERBERT J. PATERSON, C.B.E., M.Ch., M.A.,

M.B. Cantab., F.R.C.S.,

Senior Surgeon, London Temperance Hospital.

It is indeed a sign of the times that a subject should have been chosen for discussion in the Surgical Section of the British Medical Association which only a few years back was referred to in the medical press in such terms as "meddlesome and dangerous surgery," and "an unnecessary and unjustifiable operation." It seems, however, that the council of the Section, with that "canniness" which is appropriate to a meeting in the second city of the empire, have thought it wise to tread warily, and have camouflaged the discussion with the title of "The surgical treatment of non-malignant affections of the colon," when in reality they mean the surgical treatment of intestinal stasis, as is clear from the fact that they have selected the great advocate of this treatment to open the discussion.

Sir Arbuthnot Lane has been a pioneer in the subject of disorders of the colon, and has not escaped the fate of those who advocate revolutionary proposals. I remember when I was a student, a great surgeon and teacher was accustomed to hold up Sir Arbuthnot Lane as a terrible warning and example of a brilliant surgeon with a mental twist in regard to the treatment of fractures. In later times it has been assumed by many that the various kinks and other abnormalities described by him are the figments of disordered cerebration.

Sir Arbuthnot Lane has received much hostile criticism with characteristic imperturbability and indifference, and although for years he was as one crying in the wilderness many of those who came to curio have remained to bless.

There are still some who scoff at the idea that there is even any necessity for surgical treatment in intestinal stasis, and maintain that medical treatment is all that is required. Of such I would say that such an attitude of mind is a tribute, not to the soundness of their judgement or the adequacy of their treatment, but rather an indication of the ease with which their consciences are satisfied.

In many cases the kinks described by Lano are so obvious that one wonders why we failed to recognize them, and, contrary to what has been said by Sir Henry Gray, it is difficult to believe that they are other than acquired.

Although we may not all follow Lano along the whole of the road he has travelled, we must admit that he has taught us the great truth, that toxæmia due to intestinal stasis may produce serious disorders in the working of the human organism. I say "may produce" advisedly, because there may in some cases be a very great degree of stasis without any obvious inconvenience or damage to the individual. In connexion with intestinal toxæmia we should not forget to associate with Lano a distinguished Scottish physician, one of the many alumni of the north who have come south. I refer to Dr. William Hunter, whose work on pernicious anaemia has proved so valuable and so suggestive.

I will deal very briefly with three points:

1. Is there any proof that intestinal stasis causes the symptoms alleged?
2. What are the indications for surgical treatment?
3. What surgical procedures may be employed?

1. *Is there any proof that intestinal stasis produces the symptoms alleged?*

I will deal very briefly with one point, to which attention has not been called before. In many cases of intestinal stasis the symptoms are mainly gastric—flatulence, distension, pain shortly after food, occasional vomiting, and in some cases even gastrostaxis—a clinical picture which formerly was regarded as diagnostic of gastric ulcer.

Examination of the gastric contents of these patients reveals almost always a total absence of free hydrochloric acid. Now, if the stasis be relieved by a short circuit, not only are the gastric symptoms improved, but in many cases there is a return of the secretion of free hydrochloric acid. This sequence is so frequent that I think we are justified in regarding it as strong proof of the interrelation of the gastric secretion and intestinal stasis. I think it is probable that the secretion of hydrochloric acid is inhibited by some toxin absorbed from the alimentary canal.

2. *What are the indications for surgical treatment?*

What degree of intestinal stasis requires surgical treatment? A rough and ready test is to give the patient a dose of charcoal and watch for its appearance in the stools. In the absence of definite evidence of a kink or of a diseased appendix I would not consider surgical treatment unless the appearance of the charcoal is delayed for at least four days (100 hours). While recognizing fully the valuable help which is given by a skilled radiologist, in these cases I do not attach too much importance to radiography, unless it be confirmed by the charcoal test. A dog should wag his own tail, but not the tail wag the dog. There is perhaps a tendency at the present time to rely so much on bacteriology, radiology, and other diagnostic methods, that they are allowed to outweigh and even contradict the deductions from clinical observation—in other words, the radiological tail is wagging the surgeon. The surgeon should wag his own tail.

3. *What surgical procedures may be employed?*

When there is evidence of definite kinks or obstruction by bands clearly surgical treatment is indicated. When the stasis is due to atony of the large bowel or a large mobile caecum, medical treatment should have had a prolonged and thorough trial and have failed before surgical treatment is considered. Of such cases in my experience there are few which cannot be relieved by medical and mechanical treatment. It is only in the severe and worst cases that surgical treatment is indicated. There are six surgical procedures which may be adopted:

1. Division of bands.
2. Ileo-sigmoidostomy.
3. Partial excision of the large bowel.
4. Total colectomy.
5. Fixation of the ascending colon.
6. Colonic excision.

1. In my experience division of bands is a most satisfactory operation provided the bands are not very extensive. The kinks are permanently relieved, and I have had a number of opportunities, when the abdomen has had to be reopened for other conditions, of proving that the bands are not re-formed. If the bands are extensive I consider that their division is a dangerous operation, apt to be followed by severe and dangerous post-operative ileus. In such cases the operation of colonic excision, to which I shall refer later, is preferable.

2. In my experience ileo-sigmoidostomy is an unsatisfactory operation. The results in some of the cases are brilliant, but in many faeces accumulate in masses in the short-circuited ascending and transverse colon, and give rise to pain and in some cases to toxæmia. I have performed this operation on 41 occasions, and in 20 of them I found it necessary later to remove the colon above the short circuit.

3. Partial colectomy, in which the divided ileum is anastomosed to the transverse colon, and the caecum, together with the ascending and half the transverse colon, is excised. I advocated this operation in a paper read before the Surgical Section at the Annual Meeting of the British Medical Association in 1913. The results of this operation, so far as the relief of symptoms is concerned, are excellent; but after a year or two one learnt that portions of small intestine were prone to become adherent to some of the many tags of ligatured omentum, and result in either acute or chronic intestinal obstruction. I have performed this operation 27 times, and in 6 of these cases an operation was necessary later for the relief of intestinal obstruction.

4. I have never performed a primary total colectomy for intestinal stasis. In my judgement the operation is inadvisable for the same reason as partial colectomy—namely, the danger from the adhesions of intestine to the tags of omentum. Of the 20 patients on whom I had to perform total colectomy subsequent to ileo sigmoidostomy, 6 later on had intestinal obstruction, 5 were operated on and recovered, and 1 died without operation, out of reach of speedy surgical treatment. Until we discover some means of preventing adhesions I think we must regard total colectomy as an operation the remote risks of which are too great to permit of its use in the treatment of intestinal stasis.

5. Fixation of the ascending colon has been discussed so fully by Mr. Waugh that I need not dwell on it. My personal experience of it is limited to two cases. It is not without its difficulties and its danger, and I confess from what I have seen and heard that I am sceptical of its value.

6. After the war I began to perform what may be termed colonic exclusion for severe cases of colonic atony and kinks caused by bands too extensive for safe division. So far as I am aware this operation has not been advocated before for intestinal stasis. The technique of the operation is as follows.

Technique of Colonic Exclusion.

Incision in middle-line three and a half inches long. Ligature and divide mesentery and terminal ileum for distance of one and a half inches, four to six inches from ilio-caecal valve.

Crush ileum at this interval with powerful crushing clamp. Tie two catgut ligatures round ileum, one at each extremity of the crushed portion.

Divide the intestine between the two ligatures with the actual cautery. Leave catgut ligature on distal portion of ileum long, cut catgut ligature close on proximal portion. The stump of distal portion of ileum is invaginated by a peritoneal purse-string suture.

The proximal portion of ileum is now anastomosed laterally to the sigmoid colon. The stump of the ileum is inverted by a peritoneal thread suture, commencing at the mesenteric border half an inch from the end of anastomosis and continued diagonally to such a degree that the end of ileum is flush with distal extremity of the anastomosis. In this way no projection of the blind end is left.

The sigmoid mesocolon is ligatured and divided for a distance of two inches, one inch above the anastomosis. The sigmoid colon is crushed in the portion separated from its mesocolon. Two catgut ligatures are tied round the crushed intestine one at each extremity of the crushed portion. The intestine is divided between the two ligatures by the actual cautery. The stump at one end of the divided colon is then buried by a peritoneal thread suture, passed diagonally, commencing at the mesocolic border, one inch from the end of stump. The gap between the mesosigmoid and mesentery of ileum at site of anastomosis is closed by a continuous thread peritoneal suture.

The appendix is brought out through a stab wound in the linea semilunaris, and secured to the edges of the skin by two sutures. The appendix is cut off just above level of skin and a large catheter passed into caecum and tied in.

If the appendix has been removed previously the caecum is brought into the stab wound and secured to the skin by two sutures and a catheter tied in.

I have performed this operation on nineteen occasions. One patient died from the operation sixteen days later from suppuration in the right iliac fossa, the cause of which was not obvious. Of the remaining 18 patients the result has been excellent in 16. One patient has had from time to time slight attacks of pain apparently due to distension of the caecum with gas, as the pain is relieved by passing a catheter into the opening of the ileum. One patient died eighteen months subsequent to operation from chronic perforation of a gastric ulcer resulting in a large intra-abdominal abscess.

This operation, it appears to me, has all the advantages and none of the drawbacks of total colectomy. It is a less severe operation than total excision of the colon; the mortality rate should not be more than 2 or 3 per cent.; nothing is removed; but above all there are no raw surfaces or tags left behind to lead to intestinal obstruction later. I venture to think that it is an operation which merits trial in those severe cases of intestinal obstruction which do not yield to medical treatment.

Magna est veritas et praevaleret. I believe that time will confirm the truth of the principles which Lane has taught us, although more knowledge may modify the methods of treatment he has advocated with such brilliance and enthusiasm.

V.—A. J. WALTON, B.Sc., M.S., F.R.C.S.,
Assistant Surgeon, London Hospital.

[Abstract.]

MR. A. J. WALTON said that he had no fixed views on the question; his disagreements with Sir W. Arbuthnot Lane were on small points in detail and not on the main principles. His first point was that these kinks and bands were not so frequent or so common as had been suggested. In the next place they were mostly congenital: he found bands and membranes in quite young children. The symptoms of that intestinal disturbance were present clinically in women chiefly (he thought 80 per cent. were women), but the bands and membranes were equally common in males and females. As to ptosis, the position was that if 50 per cent. of people were born with membranes or bands those without ptosis had no symptoms, those who developed ptosis presented symptoms. Many women who had had frequent pregnancies had profound degree of ptosis but no symptoms. He thought that they were finding the development of visceroptosis much more commonly in young women now than formerly, and the explanation was that in muscular development young women were approximating much more to the male type than to the female, and that the more muscular they became the more apt was the formation of visceroptosis. He reminded them of Sherrington's theories as to the two muscular groups: static or involuntary, and the voluntary. Young women to-day were neglecting their static muscles. In regard to the relation between this condition of intestinal stasis to secondary lesions of the intestinal canal his view was that ptosis or stasis was in no way the cause of duodenal ulcer or gall stones. Only 10 per cent. of his 500 cases of duodenal ulcer or gall stones presented stasis, and over 70 per cent. of his cases of gastric or duodenal ulcer were in males, whereas 80 per cent. of his operations for stasis were in females. Stasis was not the cause of gastric ulcer, though it closely resembled it in symptoms. There was no relief to stasis, in his view, in removal of appendix or fixation of caecum. In regard to treatment, operation should not be performed in early cases of stasis. It was a medical disease, and operation should be performed only if medical treatment had absolutely failed and only in very advanced cases. Most of these cases of stasis gave rise to symptoms various in their effects, resembling gall stones or chronic appendix or gastric ulcer, and they had to make accurate differential diagnosis between these conditions. He limited fixation of viscera to cases in which the symptoms were confined to those viscera.

THE OPERATIVE TREATMENT OF DIFFICULT HERNIAS.

BY

H. S. SOUTTAR, C.B.E., F.R.C.S.,
Surgeon to the London Hospital.

OF the many problems which arise in dealing with a difficult hernia perhaps the most important is that of closing the aperture securely and permanently. For this purpose the normal supporting tissues of the region may be unavailable, either having entirely atrophied or being so thin and delicate as to tear on the first attempt at suture and to be quite useless for repair. Overlapping operations are severe in execution and necessarily involve serious distortion of the abdominal wall, whilst the difficulty of the procedure is increased by encroachment on the abdominal cavity. In some cases the difficulty had been overcome by the introduction of perforated plates of celluloid or aluminium, and the wire filigree of McGavin have achieved conspicuous success. These methods, however, involve the introduction of a foreign body which can never in any sense be assimilated by the

tissues. The ideal solution of the problem demands some material which, whilst it is not absorbed, is so far assimilated by the tissues as to become an integral part of them, providing a scaffolding around which fibrous tissue may be laid down, but preventing the stretching to which such tissue is liable. I believe that we possess such a body in mercurialized silk.

This material was introduced by Lauge some fifteen years ago for the construction of artificial tendons and ligaments. He directed that thick floss silk should be boiled for an hour in 1 in 1000 mercury perchloride, in order thoroughly to impregnate it with the salt. It was then dried and kept in sterile parolein, in which the salt is insoluble. The resulting material is hard and wiry, and I find it a great advantage to substitute mercury biniodide for the perchloride. As drying the silk under aseptic conditions is troublesome I transfer it for dehydration to a 1 in 1000 solution of biniodide in absolute alcohol, from which it is finally transferred to sterile parolein. Silk thus treated is perfectly soft and flexible, whilst it retains its full tensile strength. When introduced into the tissues it sets up no irritation, and it has the curious property that although it is not absorbed it is so absolutely assimilated that the resulting structure is a close imitation of normal tendon or aponeurosis, possessing, however, the great advantage that it will never stretch. Microscopic sections show the strands of silk impregnated with fibrous tissue cells, the whole forming substantially a single structure.

The method of darning hernias was, I believe, first suggested by Sampson Handley in 1918, and I can only attribute the limited use which has been made of it to the absence of a suitable material. The facility with which ordinary silk may become infected is notorious, and the introduction into the tissues of the many yards which may be required involves considerable risks, for if it should become infected its removal is a serious matter. In any case plain silk is in many cases not assimilated by the tissues, and we have all found knots of silk ligatures encysted in old wounds. I have now used mercurialized silk for several years, and in no case have I seen any sign of irritation, nor has it ever been necessary to remove the silk.

The closure of hernial orifices by this method is exceedingly simple. If a peritoneal sac existed the margins are drawn together, care being taken, if necessary, to retain a portion of the sac sufficient for the purpose. The method we are describing is quite satisfactory in the case of landslide hernias in which no true peritoneal sac exists. The surrounding tissues are so far defined as to provide an adequate attachment, and the opening in the muscular abdominal wall is now darned by means of interlacing strands of silk, running from side to side of the aperture, through the margins of which they pass. These strands are so arranged

as to form a net with meshes perhaps a quarter of an inch square, every opportunity being taken to bury the strands in any tissue which may be available. No attempt is made to close the aperture by dragging the sides of the opening into apposition, only such tension being applied as will bring the margins to their normal anatomical position. It will usually be possible to cover the net with some remnant of the fibromuscular structures of the wall, but if this is impossible a substantial covering of skin and subcutaneous fat will suffice. In most cases of this description the latter tissue at least will be present in sufficient quantity.

I have closed very large apertures by this method, a defect six inches in diameter being in one case filled. The advantages of the method are its extreme facility, the avoidance of extensive dissection and of traction, with a resulting absence of shock, its applicability to every conceivable form of hernia, and the security of the result. A remarkable feature is the normal appearance of the abdominal wall. After several months the aperture has become so perfectly obliterated that in more than one case it has been difficult to convince oneself that it ever existed.

From a series of large hernias so treated I should like to describe two as typical of the results one may expect to obtain:

CASE I.

A woman of 55 had six years previously been operated upon at another hospital, a large ventral hernia resulting. For five days she had had severe abdominal colic, vomiting, and absolute constipation. She was a very stout woman, with a gigantic, tense, irreducible ventral hernia. On operating, two large sacs were opened containing large and small gut, the latter distended and obstructed. With a good deal of difficulty the gut was freed and returned, and the peritoneum closed. There was a gap of fully six inches between the recti, the wall consisting of scarcely more than skin and peritoneum, with a little fat between. The whole space was darned in the manner described. Seven months later there was a sound abdominal wall between the recti. There was no sign of a hernia, she was in perfect health, and had no discomfort of any kind.

CASE II.

A man of 61 had a gigantic bilateral inguinal hernia of ten years' standing. The scrotum hung down almost to his knees, and as he was a vagrant it will be understood that he was not an attractive surgical risk. Under spinal anaesthesia the hernias were reduced by open operation, the chief difficulty in reduction being the lack of room in the abdominal cavity to accommodate the contents. The sacs were closed in the usual way, and the large apertures remaining in the abdominal wall darned with mercurialized silk, no attempt being made to bring the margins into actual approximation. The man made a normal recovery, and five months later he was perfectly well and the abdominal wall was absolutely sound.

These cases are merely illustrations of a method of wide application. It is difficult to imagine a hernia which could not by those means be brought under control.

THE BACTERIA OF THE TONSILS AND ADENOIDS.

BY

NELLIE WALL, M.Sc., M.B., Ch.B., D.P.H.,
M.R.C.S., L.R.C.P.

(From the City Laboratories, Liverpool.)

THE results recorded in this paper were based on an examination of the tonsils and adenoids removed by operation on children under 16 years of age at the out-patient department of the Royal Hospital for Sick Children and the school clinics.

The specimens were collected by the observer, and examination was begun generally within one hour of collection. All the specimens showed hyperplasia, but no evidence of acute inflammatory or any other special pathological conditions visible to the naked eye. The object of the investigation was to determine the bacterial flora of the tonsils and adenoids in ordinary hyperplasia, and to estimate the frequency with which they are infected by *B. tuberculosis*.

A culture was first made from the surface, then, after canterization with a hot scalpel, a second culture was made from the bottom of the crypts by means of the platinum loop.

Cultures were made on (1) nasagar slopes, (2) nasagar slanted with human blood, and (3) blood serum slopes. The remainder of the specimen was then minced as fine as possible with scissors, pounded in sterile normal saline and completely macerated. This mixture was treated with 33 per cent. antiformin and incubated for two hours at 37° C.,

centrifuged for half an hour, and the supernatant fluid poured off. Sterile saline was next added and centrifuged again. This process was repeated two or three times to eliminate all traces of antiformin. The fluid was then inoculated subcutaneously into the groin of a guinea-pig. At the end of six weeks the animal was killed and examined for enlargement of glands at the site of inoculation, for any other glandular enlargement, and for evidence of *B. tuberculosis* in these glands or in any of the organs. Films were made from the enlarged glands and stained by the Ziehl-Neelsen method and examined for acid-fast bacilli. Sections in paraffin were made from the remainder of the glands and examined for any evidence of infection with *B. tuberculosis*. If nodules were found to be present in any organ they were also examined histologically.

Bacillus tuberculosis.

The inoculations made from tonsils or adenoids numbered 170 (120 patients). Three of these inoculations revealed the presence of *B. tuberculosis*; in each case the examination was tonsillar, and the examination of the adenoids gave a negative result. The percentage of positive cases was 2.5. In the positive cases there was no clinical evidence or history of tuberculosis.

Forty-three adenoids and 37 tonsils were examined for other bacteria with the following results.

Diphtheroids.

Blood serum was used as the culture medium, and films from these cultures were stained with methylene blue, Neisser's stain, and Gram's stain. Bacilli which were Gram-positive and which showed the presence of granules with Neisser's stain and with methylene blue were classified as diphtheroids. The pathogenicity was tested in many cases by inoculations into guinea-pigs. None

of those tested were pathogenic to these animals. Diphtheroids were present in 30 per cent. of the cases. They were obtained from the superficial surface of 24 per cent. of the tonsils and 9 per cent. of the adenoids, and from the depths of the crypts of 15 per cent. of the tonsils and 11 per cent. of the adenoids.

Streptococci.

Nasgar smeared with human blood was used as the culture medium. The colonies were examined with reference to the following properties: solubility in bile, fermentation of inulin, and haemolysing power. They were all insoluble in bile and did not ferment inulin. The haemolytic property was tested by direct examination of the plate and again by adding a pure broth culture of the streptococci to the washed red blood cells of the sheep. They were classified according as they gave complete haemolysis, partial haemolysis, or no haemolysis.

Group I was found in 84 per cent. of the cases, and was obtained from the superficial surface of 37 per cent. of the tonsils and 11 per cent. of the adenoids, and from the depths of the crypts of 89 per cent. of the tonsils and 53 per cent. of the adenoids.

Group II was found in 34 per cent. of the cases, and was obtained from the superficial surface of 13 per cent. of the tonsils and 9 per cent. of the adenoids, and from the depths of the crypts of 16 per cent. of the tonsils and 27 per cent. of the adenoids.

Group III was found in 92 per cent. of the cases, and was obtained from the superficial surface of 75 per cent. of the tonsils and 90 per cent. of the adenoids, and from the depths of the crypts of 64 per cent. of the tonsils and 67 per cent. of the adenoids.

The streptococci giving complete haemolysis were more frequently present in the depths of the crypts of the tonsils and adenoids than on the surface. This strain is usually considered to be the most pathogenic, hence the removal of this organism by swabbing alone is difficult, and its appearance on swab culture would be relatively infrequent. Streptococci giving no haemolysis are of frequent occurrence, being present in nearly all the specimens examined.

Pneumococci.

Nasgar smeared with human blood was used as the culture medium. The colonies were examined as regards bile solubility, haemolytic properties, or inulin fermentation. They were found to be bile-soluble and capable of fermenting inulin, and showed no power of haemolysis. They were not classified further. Pneumococci were present in 56 per cent. of the cases, and were obtained from the superficial surface of 46 per cent. of the tonsils and 44 per cent. of the adenoids, and from the depths of the crypts of 40 per cent. of the tonsils and 41 per cent. of the adenoids.

B. influenzae (Pfeiffer's Bacillus).

Nasgar smeared with human blood was used as the culture medium. Colonies were found in some cases. Film consisted of short Gram-negative bacilli, and were considered to be the *B. influenzae*. They were present in 18 per cent. of the cases and were obtained from the superficial surface of 10 per cent. of the tonsils and 13 per cent. of the adenoids, and from the depths of the crypts of 8 per cent. of the tonsils and 9 per cent. of the adenoids. It was further noticed that those colonies present were usually adjacent to the more closely packed colonies of streptococci.

Dr. Shri Kant, working independently in this laboratory, made similar observations. At the time of examination the city was free from an epidemic, hence normally the *B. influenzae* does not frequently inhabit the tonsils and adenoids of children.

Meningococci.

Nasgar smeared with human blood was used as the culture medium. Minute transparent colonies were obtained in a few cases which, on examination by a Gram-stained film, had the appearance of meningococci. They were further inoculated into sugars, and gave acid in glucose and maltose, but did not ferment galactose and saccharose. Subcultures on nasgar showed no growth. These colonies were considered to be meningococci and were found in 8 per cent. of the cases. They were obtained from the superficial surface of 5 per cent. of the tonsils and 2 per cent. of the adenoids, and from the depths of the crypts of 5 per cent. of the tonsils and 2 per cent. of the adenoids. Hence the meningococcus is rarely present and is a more frequent inhabitant of the tonsils than of the adenoids.

Bacillus coli.

Nasgar was used as the culture medium. The greyish-white colonies were subcultured on to bile salt, neutral red lactose agar, red colonies being formed. They were further examined as regards motility, production of indol, and fermentation of certain sugars. They were found to be motile and produced indol. They gave acid and gas in lactose, saccharose, maltose, glucose, and mannite, and acid and clot in litmus milk. They were considered to be *B. coli communis*, and were present in 8 per cent. of the cases. The bacillus was never obtained from the adenoids. It was obtained from the superficial surface of 10 per cent. of the tonsils and from the depths of the crypts of 6 per cent. of the tonsils.

The remaining organisms found were *Micrococcus catarrhalis*, *Staphylococcus aureus*, *Staphylococcus albus*, *Micrococcus flavus*, *Pharyngeus siccus*. They were classified by means of their cultural characteristics, Gram stain, and fermentation of sugars.

Micrococcus catarrhalis was present in 94 per cent. of the cases, surface of 97 per cent. of the tonsils, and from the depths of the crypts of 94 per cent. of the tonsils and 72 per cent. of the adenoids.

Staphylococcus aureus was present in 56 per cent. of the cases, and was obtained from the superficial surface of 54 per cent. of the tonsils and 41 per cent. of the adenoids, and from the depths of the crypts of 27 per cent. of the tonsils and 16 per cent. of the adenoids.

Staphylococcus albus was present in 50 per cent. of the cases, and was obtained from the superficial surface of 35 per cent. of the tonsils and 11 per cent. of the adenoids, and from the depths of the crypts of 16 per cent. of the tonsils and 11 per cent. of the adenoids.

Micrococcus flavus was present in 66 per cent. of the cases, and was obtained from the superficial surface of 43 per cent. of the tonsils and 44 per cent. of the adenoids, and from the depths of the crypts of 24 per cent. of the tonsils and 39 per cent. of the adenoids.

Pharyngeus siccus was present in 28 per cent. of the cases, and was obtained from the superficial surface of 10 per cent. of the tonsils and 23 per cent. of the adenoids, and from the depths of the crypts of 11 per cent. of the adenoids.

It was observed that in every case fewer colonies were obtained from the adenoids than from the tonsils, and fewer varieties of organisms.

The observer wishes to express her indebtedness to Professor Beattie, in whose laboratories the work was done, to Mr. Leathart, honorary surgeon to the Children's Royal Infirmary, to Mr. Courtenay York, honorary surgeon to the Northern Hospital, and to Mr. Horace Mather, honorary surgeon to the Birkbeck Children's Hospital, for their kindness in placing specimens at her disposal.

THE CLINICAL THERMOMETER IN THE PREVENTION OF PULMONARY TUBERCULOSIS.

BY

E. CLARK-JONES, M.R.C.S., L.R.C.P.,
MUNSTER, NEW-YORK.

DISEASE as we see it in great hospitals is, in a majority of the cases, incurable. To go forward we must go back—behind the physical signs which, until recently, have been almost the sole criteria of disease, to the realms of early symptoms, whose importance the pioneer work of Sir James Mackenzie is impressing upon discerning minds. To no disease do these principles apply with greater force than to pulmonary tuberculosis.

Much thought and ingenuity have been expended upon the problem of how to scotch the invader before it has had time and opportunity to pass our defensive systems and entrench itself in the pulmonary tissues. The stethoscope, even in the ears of the expert, has had to go. To realize its impotence to detect the first inroads of the disease we need but to remember that the lung may be the seat of an extensive pneumococcal infiltration without producing physical signs, if the disease be deeply placed.

Unfortunately, efforts in other directions have introduced elements of risk without eliminating uncertainty. My purpose is to urge the claims of the clinical thermometer, understood and properly used.

At the outset let me emphasize two elementary facts: (1) a distinctive characteristic of active tuberculous infiltration is fever of varying degree; (2) the vast majority of civilized persons is infected with the disease at some period, commonly in early life.

It appears reasonable, therefore, to assume that a very large number of cases of anomalous feverish attacks both in children and adults are due to infection by the tubercle bacillus. How often do such cases occur in the experience of every medical man? Fever, headache, nausea, malaise, perhaps some cough; no physical signs: diagnosis, "influenza"—a word probably responsible for more deaths than the disease itself—or "an anomalous feverish attack due to some toxin." The commonest, the universal toxin is that of tubercle. It is argued that the patient recovers in a week, and that tubercle is a chronic, persistent affection. But does the patient recover in a week, and is tuberculosis so obstinate in its first manifestations? If it were the whole population would be in bed. Tubercle is, perhaps, of all diseases the most amenable to treatment in the great majority of cases, if promptly recognized and dealt with. But what it lacks in initial severity it compensates for by subtlety. It can appear in many guises, and may relax its grip sufficiently to convey the impression that the illness is over; but each successive attack is a little more obstinate than its predecessor, each intervening is a little more comparative health a little more difficult of attainment, until suddenly comes the knock-out blow and the ensuing struggle, either hopeless from the start, or resulting, at best, in comparative restoration of health after a weary fight of months or years. This tragedy the thermometer,

rightly used, would have prevented, by demonstrating the slight persistent fever, and thereby ensuring rest.

In cases of illness the thermometer is in great measure the final court of appeal, but by misusage the instrument is prevented from affording the help of which it would otherwise be capable.

In the first place, ignorance obtains as to what constitutes a normal temperature; and secondly, the means adopted to register the body heat are inadequate. The normal temperature is almost always assumed to be 98.4° F., but a record normal at one period of the twenty-four hours or under one set of conditions would be subnormal or supernormal at another time or in other circumstances.

The late Sir G. Sims Woodhead, in collaboration with Dr. Varrier-Jones, carried out a large number of experiments in continuous rectal readings in both healthy and tuberculous persons. The records are of the first importance, though the technique is too complex for use by the general practitioner. In his report Professor Woodhead referred in several places to the teaching contained in Dr. S. Vere Pearson's paper on "The temperature as a guide to the treatment and prognosis of phthisis," which appeared in the *Lancet* of September 18th, 1909. That paper contains matter of very great value, and a real grasp of the essential points regarding the various types of temperature curve would give the practitioner a good working knowledge of the right use and interpretation of the thermometer.

I reproduce, by permission,

Dr. Pearson's diagram illustrating the four principal types of curve that may be met with.

Chart representing Normal (N), Half-Normal (HN), Half-Inverse (HI), and Inverse (I) types of temperature curves respectively.

representative of temperatures taken after rest. Without going into the differences in the normal points obtaining in different persons I think it may be stated that the morning temperature before rising should be below 98° F. and the 6 p.m. reading not above 98.6° after thirty minutes' rest.

One or two variations which may be regarded as normal are as follows: In women during the week or ten days preceding menstruation there is usually a rise of several tenths. This disappears either with the commencement of the flow or a day or two later. Exercise raises the body heat from 1° to 2° F. in proportion to the energy expended. In young children a certain amount of latitude may be allowed, their heat-regulating centres being imperfectly developed. This must not blind us, however, to the fact that, while slight causes will upset a child's temperature, we have no guarantee in a given case, without definite signs to account for the rise, that the cause is slight. Any persistent rise should be noted carefully and appropriate steps taken. Childhood is beyond all other periods that in which tuberculosis makes its first attack.

Lastly, in this connexion, there is no law in medicine, and a few persons with early lung disease have consistently subnormal temperatures. There are many complexities concerned in accurate temperature readings, but the broad outline given should enable the practitioner to safeguard his patients' health.

Finally, we must deal with the method to be adopted if the actual body temperature is to be accurately determined.

The procedure adopted practically without exception, outside of sanatoriums, is to place a thermometer in a patient's mouth, axilla, or a groin, and after a couple of minutes to

pronounce a result of 98.4° as normal—and this without regard to the time of day. It is true that in a case of marked fever any of those crude methods will give a rough idea of the actual temperature, and the higher the fever the nearer will such readings approximate to the truth. But in such cases strict accuracy is not of vital importance. It is immaterial whether the temperature of a feverish patient be 102° or 103° . What is of paramount importance is that we should know whether it has dropped to within normal limits with the subsidence of the more obvious symptoms of the illness. It is here that the methods in vogue completely fail to enlighten us. In slight rises of temperature it is necessary to keep a mouth thermometer in position for anything from fifteen to thirty minutes in order to obtain the best record the oral method is capable of yielding, especially in a cold room, and even so the actual body temperature is not obtained. In spite of these facts these two-minute records of 98.4° or thereabouts are being accepted as normal temperatures every day by virtually the whole of the medical profession.

Pulmonary tuberculosis is manifested in its earliest inroads by a feeling merely of being below par, together with a slight degree of fever, which, under present conditions, goes unrecognized.

There is one way by which these slight rises may be registered, and that is by rectal readings. Whatever the external temperature, an accurate record is obtained by a three minutes' insertion. All the temperatures given above as falling within the normal variations are records of rectal readings. The objections to the method are entirely negligible, and I have never found them to persist for twenty-four hours, even in the most sensitive and fastidious patients. Until this method is in general use we shall continue to "get upon their feet again" patients who ought to be on their backs, and who, under such conditions, would quickly and permanently restore the balance, with an increased resistance and immunity, but who, under our present illogical system, are having prepared for them a harvest of sorrow, to be reaped in months or years to come.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

ACUTE PROCTITIS CAUSING GENERAL PERITONITIS AND DEATH.

The following unusual case of general peritonitis and death recently came under my care whilst in clinical charge at the Oldham Borough Fever Hospital.

A woman, aged 35, was sent in as a case of scarlet fever as she was said to have had a rash, but on admission no rash was present, nor were there any signs of scarlet fever. She had, however, signs of inflammatory trouble in the left iliac fossa, with a temperature of 102° and a pulse of 100. Next day she was very much worse, and a surgeon and gynaecologist were called in. General peritonitis had developed rapidly, with all the usual signs, and one considered that an infected Fallopian tube was probably the *fons et origo mali*. A vaginal examination failed to reveal any very definite tumour nor any definite tenderness. Rectal examination, however, did reveal a tender area, high up anteriorly, and the original diagnosis was adhered to, on the strength of this, failing a better one.

No operation was performed, as the patient was too ill, and next day she died; a *post-mortem* operation was performed in order to elucidate matters, with the following result.

General sero-purulent peritonitis was present, with much fluid in Douglas's pouch; no specially intense inflammatory focus was observed to guide one to the cause of the trouble, and a careful examination of the hollow viscera, for possible perforation, was undertaken, but with a negative result. No other focus was discovered which might account for the trouble, either in the pelvis, abdomen, or thorax, until, as a last resort, Douglas's pouch was opened and the rectum opened out to inspection. The musculature of the rectum was acutely inflamed throughout its whole length, and was infiltrated with yellow pus. There was no sign of abscess formation, rectal or perianal, and the peritonitis was apparently due to contiguity rather than to perforation, of which there was no sign. There was no sign of haemorrhoids, fistula, or diverticulae to account for the condition, and it was strange that the patient never complained of any rectal pain or discomfort of any sort, even upon defaecation, and a rectal examination had entirely failed to suggest a proctitis. The inspection of the rectum left no doubt that the peritonitis was secondary to the proctitis, and not vice versa.

My thanks are due to Dr. Godson, of Oldham, for his help in the elucidation of this case.

W. H. DU PRE, M.B., B.S. Lond.,
Late Assistant M.O.H. for Oldham.

* Since writing this I have had the advantage of Dr. Vere Pearson's criticism. With the exception of this statement he has expressed approval of all I have written. These low temperatures he is inclined to regard as a disease, in the same way that one gets after pneumonia. At any rate they are of tubercle in the practitioner's mind. For this reason I have not deleted the sentence.

FIBROIDS COMPLICATING SEPTIC ABORTION.

The following case, of multiple fibroids complicating a septic abortion, appears to be worthy of record.

H. L., aged 39 years, a laundrywoman, had been married six months; she was well developed and gave no previous history of any serious illness. She complained of constant gripping pains in the lower abdomen accompanied by haemorrhage from the vagina. She had had amenorrhoea for three months; previous catamenia were regular but profuse, lasting six days. She said that her abdomen had enlarged during the last year; she had had difficulty with her urine for six weeks, and latterly incontinence. Pain and vaginal discharge had lasted four days, and the pain was getting very much worse.

Two pints of urine were withdrawn from the bladder, and a large, smooth, solid tumour was found reaching to the lower border of the ribs, extending three inches above the umbilicus. Per vaginam a similar tumour filled up Douglas's pouch and was intimately connected with the first tumour. The os uteri was not palpable; the vagina was elongated and pulled up anteriorly, and there was a stinking vaginal discharge. It was not possible to disimpact the posterior tumour from the pelvis. The patient's pulse rate was 112, and her temperature 99°. She was removed to Oakham Cottage Hospital, and as it did not seem possible to empty the uterus and leave it uninfected, I decided to remove the whole uterus, clamping the os in a bag of vagina, as in panhysterectomy for malignant cervix. The patient made an uneventful recovery. The mass weighed 10 lb. 11 oz.; the long axis of the cavity was upwards and forwards with a very much elongated cervix.

GEOFFREY WILSON, M.R.C.S.

Uppingham.

Reports of Societies.

PHYSIOLOGICAL EFFECTS OF LIGHT.

At a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on November 14th, a discussion took place on "The physiological effects of light." The President, Dr. W. LANGDON BROWN, was in the chair.

Sir WILLIAM BAYLISS, in introducing the subject, said that everyone was familiar with the fundamental law that light did not produce any effect unless it was absorbed by the medium through which it passed. It appeared in all the biological reactions so far investigated that energy from the light was absorbed, in some cases largely (as in the green chlorophyll of plants) and in other cases much less obviously. There were cases in which the light did not appear to impart much energy, and yet it might suffice to give the original stimulus for the starting of a process. In speaking of effects of the light he thought it more convenient, though possibly less accurate, to refer to them as photo-chemical effects (resulting in the production of some active chemical substance), rather than photo-electrical effects (in which the process was supposed to depend upon the omission of electrons). It was perfectly clear, especially from the observations on rickets and tubercle, that light acting on the skin produced something which must pass into the blood and be carried through the whole body. An important question which arose in this connexion was that of pigment. Was the function of pigment to absorb a particular wave-length of light? Did it act as a sensitizer? Hess of New York had shown that black rats were much less easily cured of rickets by light than white rats. If it were true that it was vitamin A which was concerned in the cure of rickets, it seemed pretty obvious that it ought to be possible to replace vitamin A by light. This replacement could take place to a partial extent. An animal on insufficient vitamin A could, by the action of light, grow as well as if it had a sufficiency of vitamin, but the converse of this did not hold good: by giving sufficient vitamin A rickets could not be cured in a dog kept without light. Another possible aspect of the light effect on tissues and structures must not be forgotten—namely, that the light rays passing through the skin became converted into heat rays in the blood.

Professor LEONARD HILL spoke chiefly on the question of pigmentation. The evaporative power of the skin was conditioned largely by pigment. It was the pigment layer which made the skin of the negro better able to lose heat than the skin of the white man. The sweat glands also appeared to be more active in the black skin. He related some experiments on the effect of pigmentation under sun heat, which showed that this took place better on wet than on dry skin, probably owing to the deeper penetration of the ultra-violet rays; it occurred less well in skin exposed to currents of wind, and very imperfectly in skin covered by glass. From observations on children it appeared that it was the cooling power, not

the sun, which had the greatest effect on the metabolism, though the sun had a profound effect also. The speaker had confirmed Hess in every respect as to the effect of light upon rickets. By means of light, rickety changes in the bone could be stopped altogether, without very much improvement in growth, and the animals exposed to light were also healthier looking and with a cleaner skin. Phosphorus in the blood, which was very low in the rickety subject, was increased a little—not very much—by exposure to light. A fact which might appear puzzling was that children in some tropical or subtropical countries got rickets. This was probably explained by the effect of excessive temperatures. Rats living in moist heat on a normal diet showed signs of rickets and a tendency to die of pneumonia.

Sir HENRY GAUVAIN gave illustrations of the effect of light treatment in cases of surgical tuberculosis at the Alton Cripples' Home and at Hayling Island. One difficulty he had experienced was due to the non-pigmentation of certain children. Children with a tendency to freckle and not to pigment failed to do well under light treatment, and could not indeed stand long exposures to the sun. The absence of pigmenting power was of prognostic significance. Frequently there was latent tuberculosis in such children, and a new lesion might be expected to develop or an old one to recur. When this relapse did take place the children often acquired pigmenting power and thus became more amenable to treatment. Sun treatment should not be given to children without proper arrangements to avoid blistering, and the children, by means of occupations and amusements, should have their attention diverted from the fact that they were receiving a course of treatment. The strong exposure to the light obtainable by the seashore at Hayling Island was not suitable for very young or very weakly children. It should be reserved for the stronger or those with good pigmenting power.

Professor C. J. MARTIN summarized the results of certain observations by the workers at the Kinderklinik in Vienna, which showed that in winter, among children on ordinary diet, not arranged to include a certain amount of the required vitamin, a considerable proportion developed rickets, whereas in summer the diet did not signify, for neither the children who had no cod-liver oil nor those who had it tended to get rickets. He thought that the discovery of the power of light in preventing and curing rickets was one of the most important of recent years.

Dr. ELSIE DALYELL described the treatment of rickets by mercury-vapour lamps, beginning with an exposure of five minutes daily at a distance of 100 cm., and gradually increasing the time and diminishing the distance until an exposure of thirty minutes was given daily at a distance of 70 cm. The first signs of healing in the case illustrated appeared on the seventeenth day, by which time the child had had a total exposure to the light of 1 hour 50 minutes. After a total exposure of 4½ hours, spread over seven or eight weeks, an x-ray photograph showed a restoration of the contour of the bone and apparently normal calcification proceeding.

Dr. GOLDLATT of the Lister Institute described how animals had been put on a diet deficient in fat-soluble A, and after they had definitely stopped growing for two weeks they were irradiated by light, with the result that there was a temporary resumption of growth. His conclusion was that no synthesis of fat-soluble A occurred as a result of the radiation, but that a kind of economy of the fat-soluble already stored in the animal took place owing to the light action, and that this led to a better curve only for as long as the vitamin lasted.

Dr. W. CRAMER also gave an account of experiments on animals which went to show that the effect of light was really a physiological stimulus to the mechanism which formed the platelets or blood-plates. The nature of this mechanism was not known, but if the assumption could be made that the platelets were formed in the endothelium one could understand why the light acted as it did.

At the end of the meeting a paper on a cognate subject was read by Dr. J. W. TREVAN, in which Miss E. BOOCK had collaborated. It gave an account of experiments on colour changes in frogs under the action of light. It was easy to turn a frog from dark black to yellow in the course of a few hours. The frog that had been exposed to light was definitely more susceptible to digitalis and to the group of which digitalis was a member than the frog which had been kept in the dark. Frogs which had been kept in the light were more susceptible also to quinine. It was possible that

in the mammal there was some such mechanism as that which produced colour changes in the frog; there might be nervous receptors in the skin as well as in the eye which were affected by light, and which influenced in some way the metabolism of the whole animal.

TUBERCULOSIS OF THE FEMALE PELVIC ORGANS.

THE Obstetrical Section of the Royal Academy of Medicine in Ireland met on November 3rd, with Sir WILLIAM SMYLY in the chair, when the President, Dr. BERNET SOLOMONS, read his presidential address on "Tuberculosis of the female pelvic organs." Having referred to the diagnosis and treatment of tuberculosis of the vulva and vagina, he dwelt on the possibility of infection of male by female and vice versa. The difficulty of making a diagnosis between cancer and tuberculosis of the cervix was sometimes great, and much care must be exercised by the pathologist when making his report. Tuberculosis of the body of the uterus was found as a tumorous condition or in the form of endometritis, these types were commonly associated with tuberculous salpingitis. Tuberculosis of the Fallopian tubes might be regarded as one of the common ailments among women. Dr. Solomons had sent a questionnaire to a series of 54 cases on whom he had operated, and from the answers obtained he concluded that resection of the tubes in these cases was undesirable; that complete salpingectomy was the treatment of choice; and that hysterectomy was unnecessary except when the uterus was greatly enlarged or in a state of pyometra. For abdominal tuberculosis's operation was considered the best treatment; occasionally post-operative x rays or vaccines were of benefit; but the treatment by x rays or vaccines in operable cases, or where a diagnosis had not been made definitely, was to be deprecated. The difficulty in making a definite diagnosis in cases where there was much intestinal involvement was sometimes extremely great.

Sir WILLIAM WHEELER said that he would like to thank the President and members of the Section for inviting him as President of the Surgical Section to hear a most interesting address. Tuberculous peritonitis was a very common malady, and, in the first instance at any rate, the patient consulted either a surgeon or a physician, yet in the majority of cases in females the primary focus was in the Fallopian tubes. It was interesting to note how tuberculous peritonitis arose from the Fallopian tubes, for it threw a bright light on the whole subject. In gonococcal and all infections of the tubes, except tuberculous infection, the fimbriated extremities were closed and the peritoneal cavity was safe from direct invasion; but in tuberculous infection the fimbriated extremities remained open, and the tubes spued their contents into the abdominal cavity, setting up tuberculous peritonitis. As a matter of fact, the fluid developed in the peritoneum was probably protective and defensive fluid, such as occurred early in perforated ulcers, and the real tuberculous peritonitis came on much later if the *fons et origo* was not removed. In the ascitic form, when the abdomen was opened and the fluid removed, the open ends of the tubes were closed by becoming adherent to some neighbouring viscera, and the peritonitis disappeared. The tubes then developed into pus tubes, and could be recognized as large pelvic masses, or else after years they disappeared and left behind a mass of adhesions fixing the pelvic organs. Murphy and Mayo had long ago proved those generally accepted facts. In cases of tuberculous peritonitis a certain cure could be predicted if tuberculous Fallopian tubes, or any other primary focus such as the appendix, could be removed. Adhesions appeared to occur in cases of tuberculosis in the pelvis without mixed infection, but the adhesive variety of tuberculous peritonitis above this level was always due to the entrance into the area of pyogenic organisms. These organisms were destroyed early, but the tubercle bacilli remained. Sir William Wheeler thought that the prognosis of tuberculous peritonitis depended almost entirely upon whether the primary focus could be removed. If it was not found or could not be removed the patient might recover for a time, but would succumb to tuberculosis within a few years. It was sometimes very difficult to distinguish between tuberculous peritonitis and the rupture of a small carcinomatous ovarian cyst. It was a curious thing that tuberculous peritonitis was found clinically twice as often in females as in

males, but *post-mortem* examinations indicated the reverse to be the case. This was an illustration of the difference between the pathology of the living and the pathology of the dead, and an example of why clinical pathologists were needed who were interested in the living as well as in the dead. As regards operation in cases of tuberculous peritonitis, the difficulty was to decide whether the inside of the Fallopian tube was tuberculous or not. Tuberculosis on the outside was no indication for removal, for this might be part of the general spread of the disease, from a caseating gland or elsewhere. In many other abdominal lesions the work of the surgeon and the gynaecologist overlapped. Active tuberculosis became more active and destructive during pregnancy as distinct from quiescent or latent tuberculosis, which was not affected. In conclusion, he said that they were backward in Dublin, as compared with other cities, in connexion with team work.

Dr. T. G. MOORHEAD said he felt at a disadvantage as compared with other speakers inasmuch as they were able to consider from a local standpoint, whereas it was only the general aspect which appealed to him and to most physicians. He was struck by the fact that Dr. Solomons had stated in his paper that the acquiring of mild tuberculosis early in life prevented that person from getting severe tuberculosis later on. The same thing was found in connexion with pulmonary tuberculosis. Paterson, in discussing the subject at the recent Annual Meeting of the British Medical Association, pointed out that old tuberculous lesions were rare in people who died of phthisis. This confirmed Dr. Moorhead's opinion that the best thing that could happen to children was to get a mild infection of bovine tuberculosis as early as possible. The only misfortune was that one could not control the degree of infection. As regards tuberculous peritonitis, he was glad to learn, from the remarks of the previous speakers, that surgical treatment was now practically abandoned. In his opinion, the only justification for surgery was to remove some local lesion, such as the Fallopian tubes. The idea that opening the abdomen, letting out fluid, and stirring up the contents produced cure was quite a mistake. Medical treatment gave far better results than surgical. Occasionally tuberculosis of the Fallopian tubes came before the physician as a cause of unexplained pyrexia. In such cases the diagnosis rested with the gynaecologist. Tuberculin tests, whether hypodermic or cutaneous, were quite unreliable.

Dr. W. D. O'KELLY remarked that in dealing with tuberculosis of the tubes certain points arose. In a so-called primary case of tuberculosis how did the disease get into the tubes? The tubes were not at all liable to injury. Why were they so frequently involved? With regard to the tuberculosis of the ovary, a case of this was brought to him by a surgeon, who operated for tumour of the ovary, and when shown to him it looked like a cancerous tumour of the peritoneum. He would like to know if the President had met with any cases of tuberculosis of the uterus developing after pregnancy.

Dr. GIBBON FITZGIBBON said that he had hoped to receive some information on the treatment of tuberculous disease. Sir William Wheeler was of opinion that the tubes should always be removed, but on that subject he had an open mind. He generally based his treatment on the individual case, according to whether he thought the case was one in which tuberculosis had been cured, or one in which it was active. One practically never diagnosed a case as being one of tuberculosis of the tubes. The question of operation held out in the paper that night seemed very drastic. Tuberculosis of the uterus was rare, as shown by the number of cases in which the uterus was taken away and found to be non-tuberculous. The majority of tuberculous tubes met were cases studded over on the surface. The paper that evening had been extremely interesting, and it was very valuable to them to hear the remarks of the physicians and surgeons on a subject with which they had to deal a good deal.

Dr. R. J. ROWLETTE remarked on the rarity of tuberculous disease of the uterus, at any rate as compared with tuberculosis of the tubes. He used to think that infection by coitus must be an event that occurred with a certain amount of frequency, but he could never find any evidence to support this. Though one got a good result as regards cure by operation, yet there were a great many people who had not been operated on, who recovered from the disease and lived healthy lives afterwards. The President had spoken of the rarity of tuberculosis of the ovary, but he had no suggestions to make as to why it was so rare.

town supplies. The conclusion he arrived at was that the milk supply in American towns was enormously better than in England. As a general rule it was richer, cleaner, had better keeping qualities, and was freer from the possibility of conveying scarlet fever, typhoid fever, or tuberculosis. There was a feeling among the people that the supply was a safe one. The general principles adopted to bring this about were that the supply was of good quality, all vessels were sterilized and well dried before use, the udders were cleaned, covered milking pails were used, and cleanliness was enforced. The farmer was paid for his supply on a fat basis. If the monthly average of samples taken daily was above 3.5 per cent. he received increased payment; if below he was paid less. It paid, therefore, to produce good milk. A great deal of milk was distributed in bottles, which were stoppered with a disc indicating the day of the week on which the milk was produced. The cost of production had not been materially raised by the improved methods of production, and the consumption of milk in America was about double that in England. Professor Robertson referred to the effect of pasteurization on milk and considered that the extra cost entailed by adopting this process might be met by a reorganization of the methods of distribution.

The President said that in the northern counties of England no attempts were made at pasteurization except in one or two large towns. He pointed out that the vitamins in dried milk were not destroyed by sterilizing, and urged that dirty, ill-constructed cowsheds had a demoralizing effect on the workers. Dr. T. EVANS thought there would be great difficulty in using sterilizers in many English farms. Professor KENWOOD said that there was at the present time being sold in England a large amount of pasteurized milk, which was distributed in bottles at the same price as raw milk. There was only one delivery daily, thus reducing the cost of distribution. Dr. HOWARTH suggested that there was no waste to the retailer who sold milk in bottles. He believed that the milk produced in England by the big combines was as good as American milk.

Dr. W. BUTLER thought it was a pity to contemplate a milk supply which required sophistication. If milk were produced in a cleanly condition there was little to fear from its consumption. We must have a milk that is initially clean, and not forget that contamination could be effected in the house. These views were supported by Dr. HERBERT JONES, Dr. C. S. THOMSON, and Dr. F. J. H. COURTS, the last of whom agreed that, though the ideal to be aimed at was to produce clean milk, this could only be attained by increasing its price to the consumer; he certainly did not like the idea of sterilizing dirty milk.

A MEETING of the Bath Clinical Society was held at the Royal United Hospital on November 3rd. Mr. LACE showed a specimen of a neuroma of the plantar nerve removed from a case of intractable metatarsalgia which was cured by this procedure. Dr. COATES showed two cases of dysentery, one of which showed an infection with bovine tubercle added to the dysenteric infection. Mr. FRASER showed a case of painful foot with a calcaneal spur; a case of epithelioma of the tongue, and one of suppurative dacryocystitis cured by operation from the nose. Dr. GORDON showed a case of congenital dislocation of the hip in a man of 66, and a case of infantile in a girl aged 17. Mr. MUMFORD showed two cases of congenital dislocation of the hip in children. Mr. LEVIS, in a paper on the treatment of varicose ulcer, mentioned the various methods of treatment usually in vogue, and described his own method, which he has found very satisfactory. This consists in (1) compresses of strong solution of sodium bicarbonate for a few days. (2) The limb is elevated for half an hour to two hours and painted from knee to toes, regardless of the size of the ulcer, with a solution of crystal violet and brilliant green 1 to 2 per cent. When the stain is thoroughly dry two or three ordinary 3-inch bandages well soaked in Unna's paste are applied. This may have to be repeated two or three times in the first ten days, then every three weeks to three months. The last bandage to be worn six to twelve months.

The seventeenth annual conference of the All-India Sub-Assistant Surgeons' Association will be held at Indore (Central India) in December, 1922.

The next meeting of the International Union Against Tuberculosis will be held at Berne, Switzerland, in 1924. It is proposed that the meeting in 1926 shall be held in the United States, under the presidency of Dr. Theobald Smith, director of the Rockefeller Foundation Animal Research Laboratory at Princeton.

Rebuelus:

OLD AGE.

SIR HUMPHRY ROLLESTON has turned his Linares lecture given this year at St. John's College, Cambridge, into a very interesting book, compact of matter but yet easy to read. The lectureship is one of the oldest medical foundations in England, for it dates from 1524, six years after Henry VIII granted a charter to the Royal College of Physicians, with Linares as its first president. The lectureship has recently undergone a process not dissimilar to that biologists term rejuvenescence, of which the author has a good deal to say in several of the early chapters of his book.

The title is *Some Medical Aspects of Old Age*, and in the first chapter the duration of life is considered in a general way; this is followed by a brief description of the onset of old age in man, and by discussions of the factors influencing longevity and of the causes of senescence. This part of the book is illustrated by portraits of a number of persons reputed to have attained great age. The author is properly sceptical as to the facts in the majority of the extreme instances, but his last portrait is that of Sir Henry Pitman, who was born in 1803, was for thirty-one years Registrar of the Royal College of Physicians, and died in 1908, a few months after he had become a centenarian. He was a remarkable example of the retention of mental powers into old age. Only a few years before his death and long after he had resigned the registrarship, which he did in 1889 at the age of 82, he went down to the college and made a speech as clearly delivered, as well put together, and as closely reasoned as in his best days; but it was an effort for which he had carefully nursed himself; in the most vigorous aged persons fatigue is quickly produced. Upon this Sir Humphry Rolleston has a good deal to say in several places, but particularly in the chapter on the physiology of old age, which we would particularly commend to the attention of the younger members of the profession, who naturally find it difficult to realize how the whole of an old man's life, even if he be free from any distinct manifestations of disease, is coloured not only by the slowly growing physical disabilities, but also by the decline of the power of making any continued mental effort. The inevitable loss may be hastened by psychical causes. "As the years advance, and the younger generation come up the suggestion that 'his day is done,' that he has had his innings, and that it is time for him to step aside, is made to the senior not only by his family and his juniors—hetero-suggestion—but by himself, and he may then, after the modern fashion, get into the habit of repeating mentally 'I am getting older and older every day.'" This very true observation leads on to a consideration of the injurious effect giving up work may have. In a "healthy vigorous man enforced retirement at the age of 65 or 70 is not to the advantage of either the retiring victim or the community."

Healthy—"ay, there's the rub." Sir Humphry Rolleston devotes his last chapters to the distinction between healthy and morbid old age. "Violent death in one form or another—traumatic or infective—is," he says, "so much the rule that the occurrence of natural death in the animal kingdom has been questioned." The pathology of the aged includes the damage done in the past, perhaps in youth, as well as morbid processes starting during advanced life; the author enumerates these and discusses most of the more important and frequent. When considering the influence of personal habits on longevity, diet, alcohol, and tobacco come under impartial review. While he is emphatic that there can be no reasonable doubt about the bad influence on longevity of alcohol, even in moderate amount, he rather leaves the reader with the impression that his prolonged study of the subject has brought him to the conclusion that overeating is even more injurious; it is at least significant that the life histories of centenarians show that they have usually been small eaters, especially of meat, and Lacassagne's aphorism is quoted that "the greatest dangers for an old man are a good cook and a young wife." Tobacco is dismissed with the Scottish verdict—"not proven."

Scattered through the book are many shrewd pieces of worldly wisdom; for instance, "as a kind of protest against the inevitable there may, in the early stage of old age, be a

¹ *Some Medical Aspects of Old Age*. By Sir Humphry Rolleston, K.C.B., M.D., President of the Royal College of Physicians of London. London: Macmillan and Co. 1922. (Cr. 8vo, pp. 176; 9 plates. 6s. net.)

tendency to ape the young and to conceal the true age; thus a man may remove the date of his birth from *Who's Who* and books of reference, and a mother may delay the coming out of her daughter." We find incidentally also some instructive clinical observations; for example, the reader is advised to bear in mind that the use of thyroid and other gland extracts having a definite effect on metabolism is not devoid of risk to cells that are gradually undergoing involution; for by stimulating metabolism unduly vitality may be exhausted, and a flash in the pan be followed by more rapid loss of function. Again it is said that "migraine usually becomes less troublesome or disappears with the march of years." Sir William Jenner, who often comforted sufferers from this distressing malady with an assurance to this effect, associated its disappearance with the decline in the activity of the sexual glands.

We have said enough to show that the book is a valuable contribution to clinical medicine, and we will repeat that it will be particularly helpful to young practitioners.

FRACTURES AND DISLOCATIONS.

The third edition of Professor HELFERMEIER'S treatise on fractures and dislocations was considered to be of such interest as to warrant the issue of a translation by the New Sydenham Society. The tenth German edition² has recently appeared and in its general arrangement conforms to that of its predecessors. There is a good deal of new material based in large measure on experience gained in the great war. The method of nail extension introduced by Steinmann with several modifications by other authorities receives favourable notice. The operative treatment of fractures in general is referred to in relation to most types, though little attempt is made to give a detailed description of methods of technique. It is also noticeable that the use of bone grafts or pegs is not referred to.

The attitude towards the treatment of fractures of the neck of the femur, in contrast to that adopted by several American and French authors, may be classified as pessimistic, though no doubt pessimism in this relationship may be deemed justifiable by many experienced surgeons.

A number of new figures have been introduced. They are chiefly radiographs, and include a useful series showing the appearance of normal joints. Most of the old coloured plates are retained, and though they appear somewhat old-fashioned they give a very clear presentation of the anatomy of various injuries. The book endeavours to cover the subject in a very complete manner, and goes so far as to include the various forms of internal derangement of the knee-joint. This encyclopaedic character in a work, compressed as it is into little over 450 pages, detracts from the practical value of the volume, for it of necessity leads to the omission of many details of methods of fixation and management which the practitioner might look for in a work of this character.

As a whole the volume gives an impression of being crowded—an impression increased by the free use of small type for the description of technical procedures and the descriptions of figures in the text. In general, however, the book may be regarded as giving an authoritative exposition of the subject from the present-day German standpoint.

LAWSON TAIT.

LAWSON TAIT died over twenty-three years ago after a very full life. This JOURNAL in an obituary notice published on June 24th, 1899, said: "To see him once was to remember always his short burly figure, his lionine head, his determined mouth, and his masterful expression. Self-reliant, possessed of great abilities, an indomitable will, a dauntless courage, and a consciousness of his own genius, he would have risen to eminence in any profession. . . . No one could meet him without feeling the influence of his strong individuality, the vigour of his thought, and the originality and freshness of his views. He took part in many fierce controversies, both in the medical and in the lay press. He was a born fighter, he revelled in the joy of conflict, and would fling himself with all the ardour of his pugnacious nature into the arena of debate."

Dr. STEWART MCKAY of Sydney has now written a rather

large book—*Lawson Tait: His Life and Work*,³ which has for its subtitle, "A contribution to the history of abdominal surgery." It contains a general account of Tait's life and work, supplemented by personal observations made whilst Dr. McKay was his assistant in 1891.

The book commences (Ch. I and II) with an account of Tait's parentage and education until in 1866 he obtained the diplomas of L.R.C.P. and S.Edin. In 1867 he became house-surgeon at Wakefield Hospital, where he had the unusual opportunity of performing five ovariectomies. In 1870 (Ch. III) he started at Birmingham in general practice, but having taken the diploma of F.R.C.S.Edin. he began to publish contributions on gynaecological subjects, based on what he had learnt from Sir James Simpson, and to advocate the establishment of a special hospital for women in Birmingham. After a public meeting a house (No. 8, The Crescent) was taken. Tait, who in 1871 had passed the examination for the F.R.C.S.Eng., was appointed surgeon; he continued to serve on the staff until 1893. Chapter IV details his first remarkable case of an enlarged ovary, containing a chronic abscess prolapsed into Douglas's pouch. The patient had suffered from the condition for many years; the result of its removal by abdominal section in 1872 was most successful. Through this case and through Battey's communication in the same year, an excessive performance of bilateral oophorectomy was brought about (Ch. XXVI).

In 1880 (Ch. XVII and XVIII) Tait made a most important contribution to the advance of surgery in his paper on the treatment of pelvic suppuration by abdominal section. His systematic writings on gynaecology began with his essay on the pathology and treatment of ovarian disease, for which he was awarded in 1872 the Hastings gold medal of the British Medical Association. The essay was published in 1873 (Ch. V and VI). Tait's final systematic work was to have been a treatise on *Diseases of Women and Abdominal Surgery*, in two volumes; the first volume was published in 1889, but the second did not appear. Tait began his communications on hysterectomy for uterine fibroids, and . . . 1874 (Ch. VII and XXX).

Simpson, Tait wrote on hospital nail hospitals (Ch. IX), and after of antagonism to bacteriology and Lister's system of antiseptics in its application to ovariotomy (Ch. XV).

Previously the dominant consideration which prevented surgical operations on the abdominal cavity had been the danger to the peritoneum of infection from without, and Spencer Wells was well advised in adopting Lister's method to prevent catastrophes. It chanced, however, that the peritoneum was tolerant of some micro-organisms, whilst the methods which Lister had introduced for compound fracture of the leg and for wiring a fractured patella, so far as the spray and the insertion of solutions of carbolic acid or mercury perchloride were concerned, proved not only unnecessary but actually harmful in the case of the peritoneum. Tait in decrying bacteriology and deductions from it was virtually trusting, though without being aware of the explanation, to the special tolerance of the peritoneum, as well as to the chance that there would not enter the peritoneum any infection which it could not tolerate (Ch. XVI and XXXII). Although he did not originate them, Tait took an important part in popularizing operations on the gall bladder and hydatid cysts of the liver (see Ch. XI and XIV); an important section of the book is contained in Chapter XII, which gives a full description with good illustrations of Tait's operation for the repair of rupture of the peritoneum. Even more important are Chapters XX and XXVIII, relating to his operations for rupture of ectopic pregnancy, which he began to perform in 1883. John Parry of Philadelphia, in his essay published in 1876, had emphasized the results of the pitiless termination of extrauterine gestation when left to itself. Besides those principal subjects, a number of others, with the advance of which Tait was concerned, receive notice in various parts of the book. Dr. McKay does not profess to be impartial, and he frankly warns his readers in the following paragraph, with which the final chapter of the book concludes:

"I have held a brief for my dead master, and I trust that I have been able to show in the preceding pages that Lawson Tait was one of the great pioneers in surgery, inasmuch as he was the real founder of modern abdominal surgery."

1922. (Cr. 8vo, pp. vii + 475; 443 figures, 61 plates. 15s.)

The reader will therefore expect to find Tait's achievements praised without much discrimination, but he will be surprised that Dr. McKay has not kept to the rule—"of the dead nothing unless good." We have said that the book is large; it must, we fear, also be said that it is not well balanced. What is good and worthy to be remembered concerning Tait is set out, but attention is diverted by the introduction of extraneous matter, such as a sketch of the history of gynaecology from the earliest times, about which Tait, when he began to write, knew little and perhaps cared no more. The account of the state of abdominal surgery and gynaecology at that time, whether in this country, on the Continent, or in America, with which Tait might have been expected to have acquainted himself, and which therefore properly finds a place in any biography of him, is rather obscured by long excerpts from papers by him, in which much that is of the highest merit is mingled with the trivialities of bygone controversies. Dr. McKay does not indicate that he has himself made any investigations to ascertain the truth or otherwise of the statements he repeats—some made by Tait himself, some by others. The book contains a chapter entitled "Personal narrative of Tait's method of work," and Dr. McKay also produces descriptions by visitors to Tait's earlier operations; they differ very little from what he himself has written, and may be considered superfluous. Whereas in earlier years Tait appeared to lead as regards surgical technique he fell behind later on. Researches in the science of bacteriology founded by Pasteur were steadily effecting a revolution in surgical procedure, represented in the earlier stages by Lister's antiseptic system, and modified later by the change which followed upon the experiments and writings of Semmelweis. The impression therefore made on visitors to Tait's operations depended upon the individual visitor's acquaintance with the influence bacteriology was already exercising on surgery. Hence the opinions expressed by surgeons who were following the guidance of bacteriology were very different from those quoted by Dr. McKay.

When Dr. McKay decided to revive some stories, why did he omit others just as well or ill founded? Surely he would have better fulfilled his object if he had restricted himself to the expansion of such accounts of Tait as those by Sir D'Arcy Power in the *Dictionary of National Biography*, by Mr. Alban Doran, and others. Why did he not limit himself to a full description of what is of permanent importance in Lawson Tait's work concerning ectopic gestation, pelvic and tubal suppuration, the repair of the perineum, and the number of other advances made?

In exhuming various passages in Tait's life Dr. McKay has done his master ill service. Chapter I, page 3, begins: "Robert Lawson Tait was born at 45, Frederick Street, Edinburgh, on May 1st, 1845. He was the son of Archibald Campbell Tait, of Dryden, who was a guild brother of Heriot's Hospital." It is then stated that his father was a lawyer and cousin of the Archbishop of Canterbury, next his mother's name and her birthplace are given, and it is added that Tait was educated at Heriot's Hospital until he entered with a scholarship the arts course at the University in 1860; yet after these specific statements Dr. McKay must needs proceed to revive the gossip that Tait was the son of Sir James Simpson, and rather emphasizes the matter by printing opposite one another (see Pl. IV and V, p. 8) photographs of Tait and Simpson. There follow various assertions, impressions, inferences: that Tait did not deny this paternity when mentioned in his hearing, and that he asserted that he had assisted Simpson on many occasions. Dr. McKay returns to this story several times without adducing any real evidence on the matter. Contemplation of the following dates might well have made him reserve his opinion. Simpson was born in 1811; in 1839 he became professor of midwifery, and in that year he married; he had nine children, and died in 1870. Tait after quitting the arts course for medicine was apprentice, pupil, and assistant to McKenzie Edwards, Lecturer on Surgery in the Extramural School; Tait claimed (cf. Tait on Lumbar Colotomy, *Lancet*, June 25th, 1898) that for about six years he assisted Simpson, beginning in 1862 (cf. Tait on the Operation of Extirpation of the Ovary, *Lancet*, May 14th, 1870) when aged 17, and at the most only in his first year as a medical student. Indeed, Dr. McKay, in Chapter I, appears to follow Tait in applying the term "assistant" to the ordinary attendance of a medical student at the professorial classes. Again, there are various references to vivisection, whilst Tait's remarks on vaccination

are omitted. In 1832 Tait read at Birmingham a paper "Upon the uselessness of vivisection upon animals as a method of research" (*BRITISH MEDICAL JOURNAL*, 1882, i, 677). In 1893, after Horsley had advocated a resolution in favour of the objects of the British Institute of Preventive Medicine, Tait said that he cordially assented to the resolution (McKay, p. 521, and Pagot's *Life of Sir Victor Horsley*, p. 214). On page 522 Dr. McKay adds, "Tait certainly made the admission, but to his dying day he still held tenaciously to his objections to vivisection." Mr. Picton, M.P. for Leicester, on April 5th, 1889, in moving a resolution in the House of Commons which has a direct bearing upon the small-pox question at the present moment, said, "Dr. Lawson Tait was not an antivaccinist; but in a paper read at Birmingham in 1892 he said that zymotic diseases were absolutely preventable by securing fresh air, pure water, and abundant light. Many towns had shown by sanitation how to drive away the disease of small-pox."

W. G. S.

"POST-GRADUATE MEDICINE."

IN his book entitled *Post Graduate Medicine* Dr. AUGUSTUS CAILLÉ presents the fruits of an experience of forty years in practice, during thirty of which he has been engaged in undergraduate and graduate teaching. As the title explains, this book is intended primarily for practitioners and advanced students. The author makes a special point of dealing with the prevention of disease and the preservation of health, rightly observing that preventive and corrective measures must go hand in hand and that a book on therapeutics should also be a guide to prophylaxis. He follows the usual lines of classification of disease under the various systems, adding sections on the non-bacterial parasitic diseases, minor ailments, medical emergencies, drug additions, and poisons and their antidotes. In order to emphasize their clinical importance, especially as regards prevention, early recognition, and treatment, a special section is devoted to the consideration of tuberculosis, syphilis, and carcinoma. Another section is given up to a survey of bedside and office technique. We lay down the book with a feeling that the author has attempted to do too much in the space of one volume. The book contains a great deal of useful information, but the standard is not uniform, and there is evidence at times of the lack of a proper sense of proportion—for instance, quite an elaborate little dissertation is given on the proper method of passing a catheter on the male, with wood-cut drawings to illustrate the position of the catheter in the urethra. Again, in the chapter on syphilis there is a very full description of the method of giving intravenous injections, but when we turn to the chapter on diseases of the heart the electrocardiograph is not even mentioned. The whole chapter on diseases of the heart is below the standard one would expect to find in a work of this nature, particularly in view of the amount of attention which has been given to cardiology during the last ten years, and the revolutionary changes in doctrine consequent thereon. Dr. Caillé pays much attention to dietetics, and gives many useful diet tables for use in various diseases; but we fail to see the scientific value of a table which purports to give the heat equivalents of an "average helping" of different articles of food. The individual's idea of an "average helping" must vary so much as to make it impossible to estimate food values on such uncertain data. The author favours an almost strictly vegetarian diet in all forms of malignant disease, as he states that the normal sulphur metabolism is upset in these conditions.

It may be said that taking the book as a whole the descriptions of signs and symptoms are somewhat too brief and sketchy, but the advice as to treatment is thoroughly sound, practical, and free from bias. The practitioner will find many useful hints in the field of therapeutics and much practical help in the correct interpretation of the results of chemical and serological tests. Dr. Caillé adopts a very sane and well-balanced attitude in regard to the proper relation of laboratory methods to clinical investigation. There is an excellent index, but it is a pity that a wiser discrimination has not been shown in the choice of the illustrations, which in some instances serve no useful purpose whatever, while the standard of reproduction falls much below that of the printing.

* *Post Graduate Medicine: Prevention and Treatment of Diseases.* By Augustus Caillé, M.D., F.A.C.P. New York and London: D. Appleton and Co. 1922. (Roy. 8vo, pp. xxviii + 1023; 172 figures. 40s. net.)

INFANT MORTALITY.

The first edition of Dr. Hugu T. Ashby's *Infant Mortality*, which appeared in 1915, greatly aided the campaign for the saving of infantile lives which was then (notwithstanding all the preoccupation of the war) in progress. The second edition,⁵ which has now been published, whilst hardly so necessary for propaganda purposes, will be welcome for the masterly survey it gives of what has been accomplished and of the manner of its accomplishment. The title scarcely conveys a true idea of the contents of the book: "infant life saving" would be more descriptive, for that is the prime object of Dr. Ashby's work. Indeed, as was pointed out in the review of the first edition (July 17th, 1915, p. 99), it is the second part of the volume which has the greater value, and it deals with the administrative measures which are directly concerned with the prevention of death among the young. The author is entitled to take some credit to himself and his book for the improvement in the infantile mortality rate for the nation, which fell to 80 per 1,000 births (or rather live births) for 1920. This figure, however, as the Registrar-General pointed out, contained a fallacy (the large increase in the birth rate for the year), and should be 85; but even this is a great improvement on the previous lowest—namely, 91 in 1916 and 1917. Dr. Ashby says in his preface: "This figure would have been thought impossible to achieve a few years ago"; and he continues: "Another good point is that the birth rate has increased; these two factors show that we as a nation are becoming more healthy." The reviewer agrees with Dr. Ashby in this conclusion, but it is possible that another opinion may be voiced by the Neo-Malthusians. Dr. Ashby is anxious about the increase in maternal mortality during the past two years, and rightly so, for even if the child live he is sorely handicapped by the death of his mother in labour. Dr. Ashby thinks the solution is improved midwifery, and specifies more ante-natal supervision and treatment as one of the means to be used. He is quite right to draw attention also to the stillbirths rate and the primi-hebdomadal (or first-week) mortality, which are both still too high. There is great need for a concentration upon the mortality in the first month at any rate, if not in the first week of life, and that must be done, as was proved at the meeting of the British Medical Association in Glasgow in July, by increasing attention to ante-natal work.

NOTES ON BOOKS.

A TWELFTH edition of Murrell's *What to do in Cases of Poisoning*⁶ has appeared under the able editorship of Dr. PHILIP HAMILL. In this edition, which is in larger print than the last, Dr. Hamill has, by judicious omissions, reduced the number of pages by ten, yet has in no way impaired the value of the book, which has been of classic interest and importance for the past forty-one years. War poisons have been wisely avoided, and the omissions include obsolete pills and potions; and there are well-known commercial and other preparations which now figure under more modern terms. Dr. Hamill has added a few new poisons applicable since 1912, the date of the last edition. We are sorry, however, to miss the page on aqua tofana, as, although unimportant in practice, its historic interest varied the condensed style inseparable from such a work; and Socrates still lacks a reference. It is surprising how much and how valuable is the information contained in so small a compass; in an emergency the presence of such a book must be most helpful. This small work should be in the possession of every medical man, and, indeed, has latterly been included as an essential part in an antidote outfit.⁷ We might suggest that a short bibliography would have added to the book's utility.

But for the war, *Aids to Tropical Hygiene*⁸ would doubtless long ago have reached its second edition, but, as Colonel BLACKHAM observes in his preface, the allied armies cam-

paigned in many tropical theatres of war, and the medical experience gained has resulted in so great an increase in our store of knowledge that he has had to rewrite the greater part of the volume. There are twelve chapters, dealing with climate, air and ventilation, water and water supplies, food, clothing, sites and soils, the disposal of refuse, disposal of the dead, insects, animal parasites, the prevention of malaria, and disinfectants; an epidemiological table of diseases; several appendices; an index completes the book. Much useful information is contained in it, and a run through it will not be without advantage even to the expert. For the student it should also prove of value in showing him what specially to study and the various points he is expected to know about. There are many useful hints which the layman could also quite well appreciate. For missionaries going abroad and out of reach of doctors it should prove of use. The sanitary part is particularly good, but the whole of the text, with a few exceptions, can be recommended.

Dr. G. W. C. KAYE, head of the Radiology Department of the National Physical Laboratory, has done well to bring out in a convenient form a clear account of *The Practical Applications of X Rays*,⁹ largely based on his Cantor lectures before the Royal Society of Arts in 1921. The text, which is comparatively short, has been most successfully and generously illustrated, the number of pages being not very much in excess of that of the figures. The first chapter deals with the nature of x rays and their relation to the electron, Moseley's law, and the generation and the detection of x rays. The x-ray bulb and the high potential generator are fully described in the next two chapters, and then the problem of the measurement of x rays is discussed in twenty pages with many tables and figures. The medical applications of x rays are rapidly summarized, the advance technique and apparatus being illustrated by two radiographs of the hand, one taken in 1896 with an exposure of twenty minutes, the other taken last year by Dr. R. Knox with an exposure of one-hundredth of a second. There is a radiograph of the finger-prints taken, according to Bégère's method, after the finger-tip had been rubbed with red lead; it shows the design of the finger-print peculiar to the individual and also the shape of the bone. The chapter on the industrial applications is fuller and contains a number of interesting examples, such as the detection of imperfect filling of stars in army signal rockets, examination of the parts of aircraft for flaws, which was introduced by the author and Dr. R. Knox during the war, and the distinction between true old masters and copies. There are two appendices, the first containing the reports of the X-ray and Radium Protection Committee, and the second the definitions of x-ray and electromedical terms approved by the British Engineering Standards Association. Dr. Kaye must be congratulated on the production of a well-written and interesting handbook.

Volume XXXIV of the *Transactions of the American Pediatric Society*¹⁰ contains thirty-four contributions on a variety of subjects. Rickets, both on the clinical and experimental side, continues to receive a good deal of attention. Hess and Unger contribute a valuable relative importance of the clinical signs, and chemical data of the disease. Drs. J. H. Hess, Moore, and Calvin examine, by strict laboratory tests, the claims of certain well-known proprietary vitamin products and find them wanting, especially in antiscorbutic properties. Drs. J. Howland and Kramer discuss the calcification of bone with regard to the calcium and phosphorus of the serum in rickets, both from clinical and experimental data. Dr. H. Heiman utters a strong note of warning against indiscriminate tonsillectomy in infancy and childhood. There is a long and careful paper on brain tumours in young children by Dr. Martha Wollstein and F. H. Bartlett. Seven cases are dealt with: all died, and in all post-mortem examinations were made. The careful detailed record of the clinical and pathological data makes this an interesting and valuable study. A number of papers record individual cases of special interest and rarity. Altogether the quality and interest of the contributions to the volume are fully up to the standard of previous years.

Dr. WILHELM STEKEL has published yet another large volume (the sixth) on *Impuls-Handlungen*,¹¹ dealing, among other subjects, with dipsomania and kleptomania. It contains a general discussion on these and allied subjects, illustrated by many cases related at great length.

⁵ *Infant Mortality*. By Hugh T. Ashby, B.A., M.D., B.C.Camb., M.R.C.P. Lond. Second edition. Cambridge Public Health Series, under the editorship of G. S. Graham-Smith, M.D., and J. E. Purvis, M.A. Cambridge: The University Press. 1922. (Demy 8vo, pp. 724; 9 figures. 15s. net.)

⁶ *What to do in Cases of Poisoning*. By William Murrell, M.D., F.R.C.P. Twelfth edition, revised by P. Hamill, M.D., D.Sc., F.R.C.P. London: H. K. Lewis and Co., Ltd. (32mo, pp. 279. 4s. 6d. net.)

⁷ *An Outfit for Immediate Treatment of Cases of Poisoning*. By C. A. Murrell, M.D. BRITISH MEDICAL JOURNAL, February 12th, 1921, p. 232.

⁸ *Aids to Tropical Hygiene*. By Colonel Blackham. London: H. K. Lewis and Co., Ltd. (32mo, pp. 279. 4s. 6d. net.)

⁹ *The Practical Applications of X Rays*. By G. W. C. Kaye, O.B.E., M.A., D.Sc., and Hall, Ltd. 1922. (Demy 8vo, pp. 128. 10s. 6d. net.)

CAUSES AND PREVENTION OF BLINDNESS.

FINAL REPORT OF THE COMMITTEE.

(Concluded from page 987.)

INDUSTRIAL EYE DISEASE AND ACCIDENT.

BLINDNESS and impairment of vision from industrial causes arise in the main from accidents; they are serious and responsible for much economic loss.

In the Scottish Register of the Blind in 1922 there was a percentage of 7.2 whose blindness was due to accidents occurring in their occupations.

The miners and engineering and metal trades headed the list in equal proportions; the greatest incidence is between the ages of 20 and 30 years. Of some 3,700 hospital in-patients suffering from the effects of eye accidents 2,336 were industrial.

Statistics were furnished by Mr. McBride of the Commercial Union Assurance Company of claims made by accident insurance companies. Of 111,000 claims 2,585, or 2.33 per cent., were eye accidents. This witness suggested that it might be assumed that in general industry 1 workman in 30 meets with an accident a year and that 1 in every 1,287 would meet with an eye accident involving injury.

Statistics are deficient on the point of the amount of loss of vision in various industries; even the figures for mines and factories are unsatisfactory. The Committee therefore recommends the pooling of information in possession of the insurance companies regarding accidents, and that this information should be made available to the Government departments concerned.

Industrial Disease Affecting Eyesight.

The principal industrial diseases that affect eyesight are various forms of poisoning, cataract in glass and iron workers, pitch ulceration, and miners' nystagmus. Apart from miners' nystagmus the number of cases of loss of vision is small. The dangers involved are, however, serious, and the relative immunity is due to the stringent precautions taken.

Lead poisoning is now rare; formerly cases of blindness due to lead were found in institutions, now there are practically none. Amongst house painters thirteen such cases were reported from 1905 to 1910, but only three since the later date. These good results are due to the removal of lead dust by exhaust ventilation, use of leadless or low solubility glazes, introduction of labour-saving devices, and the periodic medical examination of the workers by the certifying surgeon. Rare cases of blindness have been debited to poisoning by trinitrotolueno and carbon bisulphide. No authentic case of poisoning with wood alcohol is known here, but it is said to be frequent in the United States. Glass workers' cataract is not common, and it would be abolished if the workers wore the spectacles made of the glass specially devised for their use, but attempts to persuade them to do this are very disappointing. Dr. Legge, of the Home Office, said that the use of machinery in bottle making would probably eliminate the risk. Iron-workers' cataract is due to the same effects of intense light and heat, and is only to be prevented by the use of appropriate glasses. There was no evidence of injury arising from electric welding where such glasses are always worn. Pitch ulceration affecting men engaged in dealing with patent fuel is a less rare cause of trouble; goggles or crepe afford protection, but it is hoped that better methods of handling the stuff will be found. Miners' nystagmus has been so recently dealt with by a special committee that this committee deemed it unnecessary to make any inquiry, but it reproduces and emphasizes the findings of the Miners' Committee that light and more light is the way to prevent the disease.

Eye Accidents in Factories and Workshops.

The evidence shows that in factories and workshops the chief source of injury to the eyes lies in the metal and engineering trades, including shipbuilding. There are some few accidents in other trades, such as aerated water manufacture, the textile trades, and industries using chemicals.

Figures for metal workers show an incidence of eye injury from 2.5 to 5.49 per cent., according to whether light or heavy work was done. The majority of accidents are due to flying fragments of metal; these account for about 68 per cent. of cases; splashes of molten metal are the chief cause of the others. The report deals with the special measures necessary for the prevention of accidents in the several branches of the

industry and at some length. Many difficulties are involved, especially where the work done has some risk to life and limb only to be alleviated by the freest and most unobstructed eyesight. Accidents from bursting soda-water bottles are now rare, mainly due to the use of better machinery. The wearing of goggles is compulsory, but workmen are loath to wear them. In textile industries the special dangers arise from flying shuttles, but cases are "infinitesimal compared with the number of looms." Nevertheless there is room for improvement, and it is recommended that the Home Office should invite the textile industries to investigate the danger of injury from flying shuttles with a view to securing improvement in the guards.

Chemical accidents are very rare:

"We are impressed by the very low record of serious impairment of vision which the evidence reveals; such a result reflects great credit on the efforts to secure protection and treatment of those accidents that occur."

The risks of eye injuries in factories and workshops are greatly increased by defective vision in the workers; it is therefore important that corrective glasses should be used. Children under 16 years of age are examined as to fitness before entry to the factories, but over that age, with rarer exceptions, there is no eye examination. The Committee thinks this omission should be remedied. Better lighting and better screens and guards are also needed, and there is a recommendation to this effect.

Goggles and Masks.—Considerable attention is given to the use of protective goggles and masks in various industries. Often these are the best means of protection from injury; the evidence is emphatic on the point. It is, however, notorious that there is a widespread reluctance on the part of workmen to wear goggles. The employers provide them freely, but it is rare to find them on the workmen. Part of the objection arises from the bad fit of frames, and the frosting and steaming of lenses, but "there is an old prejudice, hard to remove, especially amongst chippers and fitters, that the use of goggles implies a certain lack of that skill in so cutting the metal that it will neither injure the operator himself nor a fellow worker, also a suggestion of overcaution which the younger worker rather resents." The Committee makes observations on several points in regard to the fitness of goggles for work, and recommends that the Home Office should take immediate steps to issue detailed specifications of the most suitable forms of goggles and masks for the respective industrial processes. Better goggles would mean less objection to them. The Committee looks for much help from the Joint Industrial Councils, whereby the workmen themselves will become the propaganda agents of their use, and it recommends the encouragement of the Works and Safety Committees. Ultimately it may be desirable in many trades to make the wearing of face protectors compulsory, but the time for that is not ripe.

First Aid in Factories.—The importance of securing prompt treatment of eye accidents is strongly emphasized. A trifling injury may become septic and lead to the loss of the eye. Dr. Lister Llewellyn gave details of 163 accidents; of these 44 resulted in loss of one eye, yet with prompt treatment he thought at least 33 of these might have been saved. In Glasgow Ophthalmic Hospital, of 1,000 in-patient cases of eye accidents 300 were infected corneal abrasions. A leaflet is now issued by the Home Office, which is included in every first-aid dressing-box, giving instructions for the early attention to eye injuries. In mines the position is less easy owing to the injuries occurring underground, where there can be no satisfactory ambulance provision; yet in these places injuries are very common, and lead to a large loss of working time. The aggregate of absences due to 4,340 of such accidents accounted for some 18,000 weeks. It does not appear that any sufficient protection against such accidents can be given except by some forms of face protector, but with the insufficient lighting of mines these are impracticable. With improvements in lighting something might be done. In quarries goggles are now largely worn, and their use should be extended. The provision of surface ambulance equipment to mines is extending; marked interest is shown in this connexion by managers. As an ideal it would no doubt be advisable that after every eye injury, however slight, the worker should at once proceed to the surface for first aid or medical treatment. But this is not practicable. It is advised that at least some form of provision for washing out an injured eye below ground should be provided, and the Committee recommends accordingly.

Accidents in Civil Life.

In agriculture accidents occur in hodging and ditching, in stack making, tending cattle, broadcasting fertilizers. In some of these tasks suitable goggles could be worn, but in the unorganized state of the industry it does not appear that effective measures could be taken in this regard.

In civil life there are many accidents. The risk of these is inevitable under the conditions of modern life. Their prevention, so far as they are preventable, appears to be a matter mainly of individual common sense and caution.

"We may, however, draw attention to the large number of accidents amongst children caused by forks, scissors, knives, bat pins, and similar objects, and also to the frequency of accidents from stone throwing, catapults, tipcats, etc. In view of these instances and of the large proportion of accidents occurring before the age of 16 years, we think that instruction and warning could usefully be given in infant welfare centres and schools, and that this should be reinforced by the use of suitable posters."

The war has been responsible for a large addition to the number of the blind. The number of pensioners totally blind in England, Wales, and Scotland is 1,520; besides these there are many cases of seriously impaired vision.

Sympathetic Ophthalmia.

A tragic feature of accidental injuries is the liability to sympathetic ophthalmia. The condition may arise from injuries that at first sight do not appear dangerous. Children appear specially liable to the risk. In a number of returns accounting for 4,000 cases of blindness the incidence is 2.4 per cent. The incidence has markedly diminished in recent years under modern methods of treatment, but the disease is still a serious source of irremediable blindness, and might be further reduced. An example of what can be done is given from war conditions. Mr. Ormond reported only 2 cases amongst 4,000 eye cases, of whom 780 had a damaged eye removed, whereas in the American Civil War there were 16 per cent. of cases and in the Franco-German 17.9 per cent.

"Although obviously not universally applicable, prompt removal of the injured eye eliminates all risk of sympathetic ophthalmia, and it is probably owing to this that the sympathetic ophthalmia after eye injuries showed such an extremely low incidence in the recent war."

The danger of the development of this fell disease should always be present in the mind of the medical practitioner, and all cases of penetrating wounds of the eye should be placed immediately under the observation of an ophthalmic surgeon.

The Committee emphasizes the necessity of promptitude in the diagnosis and treatment of disease and injuries of the eye. In this connexion it is necessary that there should be no deficiency in the provision available, whether in the knowledge and equipment of the general practitioner or in the readiness of access to specialist services. The Committee welcomes the beginning which has been made in the provision by certain approved societies of ophthalmic benefit for insured persons, and hopes that every effort will be made to extend such arrangements on a satisfactory basis.

TREATMENT BY UNQUALIFIED PERSONS.

A separate section is given to the consideration of the treatment of eye disease and errors of refraction by unqualified persons. The findings of the inquiry held by the Privy Council in 1908 are summarized; these show the disastrous results that may follow treatment by persons who assume such titles as "ophthalmologist," "qualified ophthalmic optician," and the addition to their names of such letters as F.I.O. or F.S.M.C. (London), which lend the public to believe that they are fully qualified medical practitioners. At the time of the Privy Council report there was a dearth of skilled medical advice in eye diseases, but the Committee reports: "The number of medical practitioners who are competent to deal with errors of refraction and diseases of the eye is rapidly increasing at the present time. This is largely to be attributed to the fact that medical inspection of school children is now being rapidly developed, and in an increasing number of schools throughout the country errors of refraction are corrected and spectacles are provided. In most areas little difficulty is now found in obtaining medical practitioners sufficiently qualified in ophthalmic work to deal with refraction in school children."

Evidence was given to the Committee on behalf of organized bodies of opticians, "that many people who test sight and prescribe spectacles are untrained and incompetent," and on that account these organized opticians desire that there should be "an official register of trained and qualified opticians."

The Committee states:

"An optician who practises ophthalmoscopy, and who advises and prescribes glasses for clients who consult him directly, poses by implication as an expert in the detection and treatment of eye defects, and claims a degree of medical knowledge which he does not possess. There is only one place where ophthalmology can be learnt, that is at a hospital, and an optician may do positive harm by prescribing glasses for cases in which error of refraction is accompanied by some disease which he is incapable of detecting. . . . Even reputable opticians . . . are liable through lack of medical training to fail to recognize diseased conditions. But unscrupulous persons who deliberately advertise themselves as competent to treat diseases of the eye are a far greater danger to the public. If such a register as is suggested were established, it would probably be difficult to prevent such persons, who might succeed in obtaining admission to the register, from posing and advertising themselves as experts competent to treat diseases of the eye."

Also:

"The public would regard the register as an official guarantee that those whose names were included in it were competent not only to provide but to prescribe glasses, and generally to deal with defects of vision from whatever cause arising. For the above reasons we are of opinion that it would be undesirable in the interests of the public to establish a register of opticians such as has been suggested. The proper function of the optician is not to prescribe glasses, but to provide them to the prescriptions of an ophthalmic practitioner, and an official register of opticians would tend to mislead the public into thinking that registered opticians were competent . . . belonging only to those who have had . . . on this question cannot be practised are based upon . . . without a knowledge of medicine."

From time to time men or women professing to cure diseases of the eye gain notoriety by the aid of specious advertisements, and thereby attract for treatment large numbers of the public. The methods adopted by these persons are many and various; some proffer special lenses, others advocate the disuse of any kind of lens, whilst others advocate the use of electricity, magnetism, and so forth. Evidence was taken concerning one of these so-called "systems."

The Committee reports:

"As our opinion has been definitely challenged in this matter we feel it our duty to record the conviction that the resort by sufferers from eye troubles to irregular practitioners who practise for gain . . . so-called 'systems' of treatment is not only futile but positively dangerous, particularly in those cases of disease in which prompt use of appropriate medical or surgical remedies is of vital importance, and where delay may entail the risk of irreparable damage to the eyesight. The Committee is also convinced from the experience of those having special knowledge of work in institutions for the blind that the circulation among the blind or nearly blind of such advertisements as were submitted by a witness does positive harm by arousing false hopes, which are doomed to bitter disappointment."

*CONCLUSIONS.**The Committee concludes:*

"It is certain that much blindness is preventable. The perfecting of medical diagnosis and technique will effect much, as will the success attending public health activity directed against unhygienic environment and conditions inimical to health. Certain factors predominant in the production of blindness in former days, as small-pox and trachoma, both dependent upon infection, have now been checked, and we have little doubt that a later generation will similarly view some present causes. Ophthalmia neonatorum and syphilis, predominant to-day, are also dependent upon infection, and although the problem of dealing with them is more complicated success in the campaign against venereal disease is, in our view, the key to the prevention of blindness from these two causes."

"Prevention of blindness from the more strictly medical aspect consists in the efficient treatment of already present disease or injury. Here the first line of defence must be the general practitioner: hence the necessity of an adequate training in ophthalmology which, in our opinion, is not at present assured. Further, in view of the frequent occurrence, in disease and injury of the eye, of cases which require the supervision of an ophthalmic surgeon, there must be facilities to ensure that specialist services are readily available. These conditions being fulfilled, there would then be the less opportunity for the unqualified practitioner, whose specious claims too often delude sufferers until the possibility of amelioration has passed."

The report gives a summary of the seventeen recommendations under the following heads: those referring to the prevention of ophthalmia neonatorum; to the educational provision of blind and partially blind children; for the better education of medical students in ophthalmology; and for the prevention of industrial eye injuries. Each of the recommendations has been given in our summary of the report.

As we have said, the report is commendably brief; it is also simply written and with a minimum of technical terms, so that its purport may be readily comprehended by all.

British Medical Journal.

SATURDAY, NOVEMBER 25TH, 1922.

MEDICAL ORGANIZATION IN SOUTH AFRICA.

IN the SUPPLEMENT this week we reproduce a letter which has been sent from the head office of the British Medical Association in London to all members of the Association resident in South Africa. The letter is signed by the Chairman of the Organization Committee and the Medical Secretary, and we may express the hope that it will be weighed most carefully by every medical man and woman to whom it is addressed. The organization of the South African profession, as many of our readers are aware, presents a difficult problem in medical statesmanship, needing for its solution, not only sound sense and wise forethought, but also goodwill, patience, and tact.

Among other difficulties the matter is complicated by racial issues; there is a considerable section of the profession and of the public in South Africa with whom the word "British" is highly unpopular. This feeling, which it would be affectation to ignore, is a factor that has to be reckoned with by the British Medical Association in its efforts to promote medical unity among our colleagues of that country. The position in South Africa is complicated also by the presence of many medical men, both British and Dutch, who belong to no professional organization, and whose apathy is unlikely to be shaken by anything that may be done by their colleagues at home or in England. Last year a referendum was taken of all the practitioners in the Union of South Africa on the question of the future organization of the profession in that country; not more than half replied. A fresh referendum is now about to be taken. In essence the question is whether, in order to secure unity of the profession in South Africa, it is necessary that the machinery of the British Medical Association in that country shall be broken up and its organization replaced by a new body, independent and autonomous but affiliated to the parent Association. Further information regarding the referendum will be found in the report of the last meeting of the South African Committee of the British Medical Association, which also appears in the SUPPLEMENT this week.

The principle of federation has been formally accepted by the Representative Body of the whole Association, and it follows that dissolution of the South African Branches and of the South African Committee, as a preliminary to federation, if desired by a sufficient majority of the members of the British Medical Association in that country, would be acquiesced in (though with great regret) by the parent body. This attitude of the parent Association, we hasten to say, has been generously acknowledged in the medical press of South Africa and in many private communications. The conditions to be observed and the several points which should be present in the minds of South African members when deciding this momentous issue are set out in the letter printed in the SUPPLEMENT. The whole tenor of the letter is governed by the closing paragraph, and this is of such importance, as a safeguard against any possibility of misunderstanding, that we quote it again in full: "It must be clearly understood that in putting these considerations before you the Council wishes, if possible, to retain its South African members as organized members of the one great Association, and it would do much to secure this. But it has no intention of withdrawing

from the offer it has made. If the members of the British Medical Association in South Africa come deliberately to the conclusion that it will be better for the profession in South Africa that the British Medical Association should disappear from that country to make room for an organization believed to be more likely to satisfy South African needs and aspirations, the Council will accept that decision loyally and will proceed with the process of federation, so that the new body may be kept in as close relation to the British Medical Association as the new circumstances will permit."

It only remains to assure our colleagues in the Union of South Africa that the one concern of the Council of the British Medical Association is to bring about a solution of this difficult problem which shall best conduce to the advantage of the profession in South Africa and throughout the sister nations.

THE CAUSES AND PREVENTION OF BLINDNESS.

IN our issues of last week and of to-day we have given a full summary of the report of a committee on the causes and prevention of blindness. Sympathy with the blind, and the sense of responsibility which the community feels for them, has been given concrete form in the Blind Persons Act of 1920, and this makes the report most opportune. All efforts must be concentrated on the prevention of blindness, for no sympathy, sentimental or practical, can make up for the loss of sight. We look to the committee's report to tell us what are the most frequent causes of blindness, and how these causes may be removed. The answer to the first question, What causes blindness? can only be reached by careful examination of the statistical information which has been gathered during many years past. The committee gathered from many sources the fullest information available, but, as with so many similar inquiries—for example, the Royal Commission on Venereal Diseases—though much labour has been given to their collection, the data rarely proved to be sufficient.

One point, however, is clear: among 25,840 blind persons (out of a total of 34,890 known to be alive in England and Wales on January 1st, 1919) no less than 21 per cent. were blinded within the first year of life. Thereafter the number was increased by almost exactly 10 per cent. for each decade of life up to 70 years. At any one time the greatest number of blind persons will be found in adult years—15 to 50—for in that period is the greatest aggregation of population. The heavy incidence of blindness in infancy brings us at once to ophthalmia neonatorum, which, according to Mr. Bishop Harman's figures, accounted for a full half of the tale of blind infants. The report shows that in recent years medical practitioners have learnt more fully to realize the gravity of the condition; that there has been a steady growth of knowledge of this disease among midwives and sanitary authorities, and that this knowledge has been reflected in practice. There is better observation of pregnant women, scrupulous cleanliness at the birth, the use of Credé's method in cases of suspicion, watchfulness for untoward symptoms in the first few days of life, and better and prompter treatment. It thus comes about that despite an increase in the number of cases notified in recent years, which is probably an effect of the greater activity with which the disease is being combated, there is good evidence that the number of cases of blindness due to this cause is diminishing. The London statistics quoted from Mr. Harman's evidence are significant. In two succeeding periods of seven years the number of children admitted to the schools for the blind was almost equal, but in the first period the percentage of those blind from ophthalmia neonatorum was

18.03, as against 11.91 in the second period. Figures were obtained from other sources, showing that there has been a reduction in blindness from this cause elsewhere. A purulent inflammation of the eyes may occur in the newborn as a result of several bacterial infections, but almost the only dangerous organism is the gonococcus; this points to the need for ante-natal treatment. So also with syphilis, which takes a heavy toll of sight by manifestations of congenital disease in children and of the acquired disease in adults. At present venereal diseases are the most prolific causes of blindness; prevent or cure them, and blindness due to them may become as rare as blindness from small-pox, that old-time destroyer of sight.

The increasing stress of highly organized modern life makes defects of vision of serious importance; hence the need for preventing damage to eyes by inflammation in childhood or by the accidents of industry in later years. Phlyctenular keratitis in children causes much injury; it is a condition dependent mainly upon poor nutrition—possibly an avitaminosis. At any rate, the best cure for it is cod-liver oil and the better conditioning which comes by a change to healthier surroundings, so that its prevention is almost wholly a matter of social organization. We can never hope completely to abolish accidents in civil life; some are so accidental as to be unavoidable—they can neither be foreseen nor prevented. But most industrial accidents may be avoided by the suitable guarding of machinery, the use of goggles, and the improvement of methods of manufacture; and, above all, by the provision of good light for all work and the selection of workpeople who can see well.

The committee does not encourage any hope of a dramatic reduction in the number of blind persons, save only among those arising from venereal disease; as the only measures available it urges that greater attention should be given to the education of medical students in eye diseases, that specialist services for the prompt diagnosis and treatment of eye defects and disease should be extended, and that steps should be taken for the betterment of social and industrial conditions where these are the determining factors. There is no short cut to the attainment of these objects. This is equally true of the regular examination of patients' eyes for lesser defects of vision, and the prescription of correcting glasses. Some would raise up a new class of minor practitioners—prescribing opticians—and register them. The committee urges, and we think rightly, that the importance of sight is such that there is no room for minor practitioners; their existence involves a major danger—blindness for the sake. To encourage well-trained

to undertake eye work there is no better way than by making official appointments for ophthalmic work part-time posts. A part-time officer gives the rest of his time and service to the general public, to the common advantage. The whole-time officer is withdrawn from private practice, and the value of his skill is lost outside his limited scope. Altogether the report of the committee is an eminently practical document which ought to have a very useful effect both on public opinion and on administrative bodies.

CHEESE POISONING.

LAST July three outbreaks of food poisoning, all attributed to cheese of Canadian origin, occurred in widely separated areas in this country—Dover, Warrington, and a village in the Newmarket Rural District. Cheese is not an article popularly associated with outbreaks of food poisoning, although there are a number of references available in the literature.¹ Vaughan reported some

300 cases with no deaths in 1883 and 1884 in Michigan. The chief symptoms described were diarrhoea, vomiting, and abdominal pain, with a certain amount of fever; rigors and collapse were often present. The incubation period, which was usually from two to four hours, might be prolonged to eight or twelve hours. In 1901 Sir George Newman, at that time Medical Officer of Health for Finsbury, reported outbreaks in Finsbury, Bermondsey, and other districts. These were attributed to cheese of Dutch origin, though nothing was found wrong in its taste, odour, or appearance. Both Sir George Newman and the wholesale merchant who sold the cheese ate some of it and were attacked. The incubation period in these outbreaks was from two to eight hours. From an aqueous extract of the cheese associated with the Michigan outbreak Vaughan separated a crystalline body which he called tyrotoxin; it resembles diazobenzene. This body was isolated also from some of the cheese associated with the London outbreaks. Other similar occurrences include two in the United States in 1886, without any deaths, tyrotoxin being found. In Aldershot² twenty-seven cases with three deaths occurred, and in addition to the usual symptoms jaundice was noticed in many of the cases. Some of the patients, however, were stated not to have eaten the suspected cheese. Tyrotoxin was found in cheese recovered from the stomachs of sheep which had eaten the remains of the suspected cheese. It is not present in all poisonous cheeses. Savage remarks, perhaps significantly, that "there are few, if any, recent references to the finding of tyrotoxin in cheese, and all these reports date from the period when the chemical and ptomaine theory of food poisoning was predominant." His view is that this form of food poisoning is usually due to the production of powerful toxins by bacteria, probably virulent strains of bacilli of the coli or Gaertner group.

In the outbreak at Dover in July, 1922, after eating Canadian cheese derived from one wholesale source, some 100 persons in about thirty families (about 90 per cent. of those eating it) were attacked; the symptoms included abdominal pains, in many cases amounting to severe colic, diarrhoea in most cases, and vomiting in many. There was a moderate rise of temperature, and a quickening in the pulse rate. The incubation period was from four to twelve hours. There were no deaths. Suspicion was not attached to any other article.

The recent Warrington outbreak, which occurred at the Union Workhouse, affected some 130 inmates, about half of those who ate some Canadian cheese; none of the staff, except the cook who alone tasted it, was attacked. The main symptoms reported were intense abdominal pain, vomiting, and diarrhoea. There were no deaths. The outbreak in the Newmarket Rural District was a small affair; about a dozen cases in some half-dozen families are known to have been attacked; possibly there were a few more. Acute diarrhoea and vomiting, with violent abdominal cramp and pains, occurred within six or seven hours.

Bacteriological examination of these cheeses by aerobic and anaerobic methods on various media yielded no positive information of value. Chemical investigations for tyrotoxin and poisonous metals such as arsenic and antimony also gave negative result. Experiments on mice gave toxic but variable results, depending probably on the distribution of the toxin in the cheese. Within varying periods, from twenty-four hours to a few days, the affected mice suffered from loose but not liquid stools, with paralysis or weakness of the hind legs; in some cases the animals are described as being wet, and ceasing to care for their appearance; two mice died with spasmodic movements of the whole

¹ See W. G. Savage's *Food Poisoning and Food Infections*, Cambridge University Press, 1920.

² BRITISH MEDICAL JOURNAL, 1899.

body, and others showed tremors. At necropsy minute or, rarely, well-marked petechial haemorrhages were found in the gastric and intestinal mucosae.

The bacteriologist (Mr. Bruce White) of the University of Bristol made feeding experiments upon himself with the raw cheese. With about 5 grains of the Dover and Warrington samples respectively, he produced illness within some seven hours. From the Dover cheese this was mainly nausea and headache, lasting for about a day, and with the Warrington cheese considerable internal discomfort persisting for several days. Alcoholic extracts of the cheese were found not to be toxic, and an extract of cheese made with distilled water for forty-eight hours at 52° C. gave with a 10-grain dose no result; both the Dover and the Warrington cheeses, extracted with distilled water, with grinding and shaking, and then filtration, produced within a few hours, when the equivalent of about 7 grains of cheese was taken, considerable internal discomfort which lasted for about two days. Various other experiments were made without positive result. It was concluded that the poison was in the nature of a protein or a true "toxin," unevenly distributed throughout the cheese. No evidence of the food-poisoning groups of organisms was found in these Canadian cheeses, nor any metallic poison or tyrotoxin.

THE SMALL-POX OUTBREAK.

The struggle continues of the public health authorities and the guardians to stamp out the severe strain of small-pox which has appeared in Poplar and various places in and near London. In a statement to the Metropolitan Asylums Board on November 18th the Chairman of the Infectious Hospitals Committee reported that since July 25th 67 cases of small-pox had been admitted, of which 22 had proved fatal, 9 had been discharged, and 36 remained under treatment. None of the fatal cases had been vaccinated since infancy. Since the date of this report another death has been recorded, and several new cases have occurred at Poplar, and one at Bermondsey. On November 21st there were 34 cases under treatment—namely, 29 from Poplar and one each from Boxley, Paddington, Bermondsey, Dartford, and Stepney. Meanwhile large numbers of prudent people are taking the precaution to render themselves invulnerable to attack, and the red band round the left coat sleeve was in evidence among M.P.s. at the reopening of Parliament. A later development is the discovery of a case on board the Canadian Pacific steamer *Montclare* before reaching the quarantine station a few miles below Quebec. The vessel had left Liverpool on November 10th. The passenger affected was from Wales, and was aged 24. He was a cabin passenger on his way to settle in Western Canada. As a result of the discovery 221 cabin passengers had to disembark for detention in quarantine, as both the emigrant and his bride had been mingling freely with the other cabin passengers. All were immediately vaccinated, together with the rest of the passengers and crew. The equipment at the quarantine station was so limited that bedding and food had to be provided from the ship, which after thirty-two hours' detention and thorough fumigation proceeded on its voyage. With regard to the difficulty which may be encountered in the diagnosis of small-pox and the dire results which may follow "missed cases" we would direct the attention of readers to the letter from Dr. Wanklyn which is published at page 1045. His experience of small-pox is probably unrivalled at the present day, and all the points he makes are worthy of the most careful attention; for, as he says, very many practitioners, and not only those in the younger years, have never seen a case of small-pox, so completely has the disease been controlled by efficient vaccination. At the same time he praises the acumen of many medical men in making a correct diagnosis in the first case of small-pox they have ever seen.

ADENOMYOMA OR ENDOMETRIOMYOMA OF THE OVARY.

For some years it has been known that islands of tissue, identical in structure with the mucous membrane of the uterus, were occasionally to be observed in the ovary; but that such islands are indeed endometrial, not only anatomically but also functionally, was first demonstrated by J. A. Sampson in a paper read before the American Gynecological Society last year. In this paper, an abstract of which appeared in our columns on February 4th, 1922, Sampson recorded 23 cases of what he called "perforating haemorrhagic cysts of the ovary." He believes that such cysts are not rare, and that when they do occur are frequently bilateral, usually densely adherent, and apt to rupture during operative removal owing to the reopening of a previous perforation which had become sealed by adhesions. Microscopic study led him to the conclusion that the cysts are due to the accumulation of blood in the gland spaces in the endometrial islands. During the present year convincing support for this view has been supplied by British gynaecologists, and the autumn number of the *Journal of Obstetrics and Gynaecology of the British Empire* contains three papers on the subject by Professor Archibald Donald, Professor Blair Bell, and Drs. Fletcher Shaw and Addis. The most interesting point emerging from these three papers is undoubtedly that Professor Donald had, from purely clinical observation, formed and expressed the opinion as long as three years ago that these "tarry" or "chocolate" cysts were related to the condition of adenomyoma. He had, however, failed to obtain clear histological proof of his view although his assistants had been investigating several specimens histologically. The first histological proof in this country was supplied by Professor Blair Bell, and immediately afterwards other cases in which the histological characters could be demonstrated were met with by Dr. Fletcher Shaw. In the cases recorded by Donald and by Fletcher Shaw and Addis there was the further most interesting feature that in thirteen out of seventeen instances the "tarry" cysts of the ovary were associated with adenomyoma in the recto-vaginal space. This is a matter of great interest clinically and may be of great importance pathologically; the frequency of the association—over 75 per cent.—is unquestionably significant. Dysmenorrhoea coming on after the age of 30 or becoming markedly aggravated at or after that age would appear to be one of the most uniform symptoms, and in general the cases are probably such as would be diagnosed as "chronic pelvic infection." Probably many such cysts have been wrongly regarded as "lutein" cysts in the past. There can be no doubt that Sampson's paper in America and the three papers to which we have referred will stimulate research into the subject, and it is to be hoped that further light will be forthcoming as to the origin of adenomyomata in general. Professor Blair Bell makes an emphatic appeal for the employment of the term "endometriomyoma" because the essential element in all these tumours is tissue which is not merely anatomically but also functionally "endometrium." The older term is, however, so closely interwoven with the early literature of the subject that it is doubtful whether the advantage of greater scientific accuracy in nomenclature will bring about its displacement.

THE HOME AMBULANCE SERVICE.

The Home Ambulance Service, organized jointly by the Red Cross Society and the Order of St. John, is steadily being extended and new ambulances are put in commission as local demands arise. The total number at the end of September was 317. During the third quarter of this year six new ambulance stations were opened, and the number of cases carried was 13,403. The increase is, we believe, in part due to the fact that members of the medical profession are becoming better acquainted with the facilities the service offers. Information regarding ambulance stations in his neighbourhood will be supplied to any medical man who cares to apply to the Secretary of the Home Service Ambulance Committee,

19, Borkesley Street, London, W.1. The ambulance can be used for the transport of patients from their homes to a hospital, or vice versa, and their aid is invaluable in accidents. Having this in mind the Committee has supplied a list of ambulance stations to road scouts and patrols of the Royal Automobile Club and the Automobile Association; both these institutions have shown a keen interest in the service and have given much help in its development. Although such a service, covering the whole country, was not thought of until demobilization placed a number of ambulances which had been in use in France at the disposal of the Joint Council, already the public has become so accustomed to the existence of the service that it has learnt to feel it a grievance if an ambulance is not immediately available. One London daily newspaper in a critical article asserted "that it is better that two ambulances should arrive at the scene of an accident than none." With that expression of opinion everyone will agree, but it is an extravagant method which ought to be avoided. Difficulties have sometimes occurred—not we believe in the case of ambulances maintained by the Home Service Ambulance Committee—owing, as is alleged, to uncertainty as to the financial liability that may be incurred by sending for an ambulance. It is clear, of course, that a national ambulance service such as has been established in England, and does not exist to a like extent in any other country, can only be maintained on a voluntary basis if due provision is made for the cost of upkeep, either by public subscription or by charging reasonable fees for the use of the ambulances. Only in this way is it possible to provide for the transport of necessitous cases outside the scope of the Poor Law, who form so large a proportion of those carried by the Home Ambulance Service. It is, however, the universal practice of those in charge of Home Service ambulances to meet calls promptly, and, if necessary, postpone questions of payment until the work is completed. Both methods of maintaining an ambulance station—that by public subscription and that by charging fees—are in use, and in some districts the two are combined. A district Motor Ambulance Association in Brecknock, which is financed by public subscription and makes no charge for the use of the ambulance, was able to show a substantial balance for the year ending May, 1922. As an example of the other method we may take the facts given in the annual report of the Sussex Branch of the Red Cross Society for 1921, where charges are made for each use of an ambulance. There was a small loss on the first quarter, and a small profit on each of the other three quarters, so that the final result for the year was that the receipts were £1,028 and the expenditure £976. We believe that any difficulties at present existing—and they are not numerous—will pass away as the system becomes better known, and members of the medical profession can do very much in this direction. Difficulties will diminish also as the system becomes more complete and co-ordinated. In this connexion we are glad to observe that a number of independent ambulance stations have become affiliated with the Home Ambulance Service established by the Joint Council. It is not possible to make any general statement as to the charges made in these areas in which the ambulance is not maintained wholly by voluntary subscriptions as the method adopted varies. In some instances a flat rate is charged within the area; in others, perhaps the majority, there is a mileage rate varying from 1s. 3d. to 2d. a mile. The local committee determines the manner and rate of payment. It should, perhaps, be added that arrangements will be made to transport patients long distances, either direct, if this be necessary, or by taking patients to the railway station at the one end and fetching them from the other.

THE CONVERSAZIONE AT THE ROYAL COLLEGE OF PHYSICIANS.

THE outside of the Royal College of Physicians, at the corner of Trafalgar Square and Pall Mall, is heavy in design and always grimy, owing, possibly, to the character of the stone of which it is built; but the interior is a very agreeable example of the domestic architecture of a hundred years ago. It was

built from the designs of Sir Robert Smirke, R.A., and was completed in 1825. The greater part of the ground floor is occupied by a large reading room and by the hall. The central staircase, which becomes double at the first landing, leads to a large library in which meetings are held. It was here that the President, Sir Humphry Rolleston, and Lady Rolleston received those invited to the conversazione given by the President and Fellows on November 21st. It was the first held since the war and was very largely attended. Opening off the large library is the room used by the Censors; it looks eastward over Trafalgar Square, and is one of the most charming examples of how architects in the early part of the nineteenth century got their effects from proportion rather than ornament. In this room are collected some of the best and most interesting of the portraits possessed by the College. Some of the manuscripts and early printed books possessed by the College were displayed, as also the silver caduceus made for Dr. John Cains in 1556, the large silver-gilt mace presented by Dr. John Lawson in 1683, and a number of other pieces. The gold-headed cane used by Dr. Radcliffe, Dr. Mead, Dr. Askew, Dr. Pitcairn, and Dr. Baillie, Harvey's demonstrating rod, and Jenner's cow's horn, as well as other curiosities, were also shown. In the theatre on the second storey nature films, lent by the Regent Film Company at the instance of Lord Ashfield, were shown.

BODY TEMPERATURE OF BIRDS.

THE essential difference between the two great groups of warm-blooded and cold-blooded animals is that the former have a constant temperature independent of their environment, whereas the latter have a variable temperature which is practically the same as that of the surroundings in which they live. This is due to the presence in warm-blooded animals of a heat-regulating mechanism by means of which the heat production and heat loss are so balanced that the body temperature remains practically constant; cold-blooded animals possess no such heat-regulating mechanism. The body temperature of birds has been made the subject of an exhaustive study by Alexander Wetmore,¹ the main features of which are analysed by Professor Sutherland Simpson in *Nature* (October 28th, 1922). The heat-regulating mechanism and normal temperature of birds has, as Professor Simpson points out, received very little attention from physiologists, so that this monograph forms an important contribution to avian physiology. Altogether more than 1,558 individuals of 327 species of birds were investigated by Wetmore, who used specially constructed thermometers of the clinical type, but with a range between 95° and 115° F. The temperatures of birds were found to present the same diurnal rhythm as occurs in warm-blooded mammals, but in nocturnal birds, such as owls, the normal rhythm was reversed, the temperature being highest during the period of activity at night, and lowest during the day—the period of rest. This diurnal rhythm would be reversed in day birds by keeping them in darkness during the day and exposing them to artificial illumination during the night—an observation which lends support to the view that the normal diurnal rhythm of warm-blooded animals is due merely to the action on the body of various outside influences, and not to a fixed periodicity of which the temperature rhythm is an expression. There appears to be no evidence of seasonal temperature variation in birds in spite of the fact that they show such marked cyclical bodily changes as are manifested by moulting and adornment with fresh plumage. As in the case of mammals the temperature of the female was usually found to be slightly higher than that of the male of the same species, and the temperature control of nestlings and immature birds was less perfect than that of adults. Very little heat is lost by radiation and evaporation from the skin, owing to the feather coating and absence of cutaneous glands, so that heat loss is controlled by the respiratory system, an important part being played by the air spaces. It holds as a general rule, though there are some exceptions;

¹ Smithsonian Miscellaneous Collections, Vol. 72, No. 19

that the higher the bird in the zoological scale the higher is the body temperature. The highest average temperature for both sexes was found in the western plover with a mean of 110.2° F. Pigeons, cuckoos, and woodpeckers stand high in the list, but contrary to general belief swallows, as a group, possess the lowest average body temperature, usually below 107° F.

RAT CONTROL.

IN connexion with the fourth annual National Rat Week a conference was held at the offices of the Holborn Borough Council on November 6th, with the Mayor of Holborn in the chair. Mr. E. C. Read (technical adviser on rat repression) to the Ministry of Agriculture) said that the geographical position of Britain made it the great centre of rat attraction, because of the goods conveyed in ships to this country and because it had the largest warehouses in the world; thus Britain harboured a large percentage of the rats belonging to other countries. In cities rats had excellent means of communication through the sewers; if the sewers were not kept clear the buildings would never be rid of rats. He suggested that the London County Council, the City Corporation, the metropolitan boroughs, and the home counties should organize one unified scheme for the treatment of sewers in that big area. He believed that as science advanced many diseases would be related to the presence of rats and mice in human habitations. In regard to rat poisons, barium carbonate and squills in various preparations were the most efficacious. Sir Frederick Andrewes emphasized the danger of using bacterial rat virus for the destruction of rats in urban districts. Up to a certain point those preparations were efficacious, but unfortunately all the animals which ate them did not die, and he had found that many of the rats that survived had acquired immunity. Of the rat viruses sold some were made from the Gaertner bacillus and some others from the Aerttrycke bacillus. A considerable number of cases of food poisoning, however, had been traced to one or other of the two bacteria he had named, so that it had not been proved that those viruses were harmless to man. Dr. F. J. Allan (M.O.H. City of Westminster) concurred in the view that if rats could be got rid of from the sewers houses would be practically free of them. The difficulty was in keeping them out of the sewers; though poison was put down time after time a great number of rats seemed to survive somehow or other. Rat-lime had been used a good deal in the City of London and other districts, and had been found very effective. Dr. G. Millson (M.O.H. Southwark) said that in his district there were ten to twenty acres of new houses, but not a single old drain had been taken up, and these formed rat runs. He had applied to the London County Council, but was told that they did not intend to do it. For catching rats he had used varnish with great success in hundreds of cases. Dr. W. M. Willoughby (M.O.H. Port of London) said that what was most necessary was to get the rat above ground and then rat-proof the food stores. If the rat lived down a drain it must come up for food and should then be cut off. The two great factors in rat increase were undisturbed nesting and access to food. Mr. A. E. Moore said that poisoning should be reinforced by rat-catching. He suggested that it was the duty of the Ministries of Health and of Agriculture to see that the whole matter of an efficient rat poison should be thoroughly thrashed out. The Mayor of Holborn thanked Dr. Hutt (the Medical Officer of Health) for his services in calling the meeting together and for bringing to general notice the extent of the rat pest.

SMALL-POX IN SHANGHAI.

SMALL-POX is endemic in China, and we learn from the Report for 1921 by Dr. Arthur Stanley, Commissioner of Public Health for Shanghai, that that city was affected by the disease in epidemic form towards the end of the year. In the whole year it caused 248 deaths, of which 204 were in the Chinese population and 44 in the foreign. In November there were 31 deaths amongst the Chinese, and in December 161.

whilst among the foreign residents in the same two months there were 23. The population of Shanghai is estimated at 804,000, of whom 24,000 are foreign, the rest Chinese. The last previous outbreak was in 1918. There is the usual tendency to ignore vaccination when small-pox is absent, but in 1921 there were close on 34,000 vaccinations, or more than had been done during the years 1904 to 1912 inclusive. Since the latter year there have been nearly 200,000 free vaccinations. Dr. Stanley insists that "China is no place for the unvaccinated. It seems necessary to give a warning to those who are responsible for bringing employees out to China that vaccination should always be done before embarkation." The death rate from all causes in Shanghai was 18.2 per 1,000 amongst foreigners and 11 amongst Chinese. Dr. Stanley's report indicates how much good work is being done by his department. In particular mention may be made of a general public health notice for foreigners published during the year. It points out the preventability of many diseases and the availability of the health staff for advice and assistance. It gives instruction as to individual measures, especially as to care in eating and drinking under the conditions of Shanghai. Nothing should be consumed that has not been recently cooked, boiled, or sterilized. Advice is afforded as to various items of dietary, because "the preventable diseases specially prevalent in Shanghai are mostly caused by infected food." Exclusion from houses of flies, rats, and mosquitos is urged, and the risks are pointed out of vegetables and fruit grown near the ground being contaminated by water containing night soil. The whole report is thoroughly practical, and shows how an officer trained in the broad principles of disease prevention can apply them to the circumstances of a foreign country and climate.

THE ROYAL SOCIETY MEDALS.

THE Royal Society has awarded one of the Royal medals to Mr. J. Barcroft, F.R.S., of Cambridge, for his researches in physiology, and especially for his work in connexion with respiration, and the Buchanan medal to Sir David Bruce, K.C.B., F.R.S., for his investigations and discoveries in tropical medicine. It has awarded the Copley medal to Sir Ernest Rutherford, F.R.S., for his researches in radioactivity and atomic structure, the Davy medal to Professor J. F. Thorpe, F.R.S., for his work in synthetic chemistry, and the Darwin medal to Professor R. C. Punnett, F.R.S., Professor of Genetics in the University of Cambridge.

LECTURES AT THE ROYAL COLLEGE OF SURGEONS.

THE Bradshaw lecture to the Royal College of Surgeons of England will be delivered by Sir William Thorburn, K.B.E., F.R.C.S., on Friday, December 8th, at 5 p.m. The subject is the surgery of the spinal cord. The Thomas Vicary lecture will be delivered by Mr. Walter G. Spencer, M.S., F.R.C.S., on Thursday, December 14th, at 5 p.m. He will speak on Vesalius and his delineation of the framework of the human body. Fellows and Members of the College are invited to attend; students and others who do not belong to the College will be admitted on presentation of their private visiting cards.

A LECTURE on the warble fly, its history and methods of exterminating it, will be given on Friday, December 8th, at 2.15 p.m., by Professor G. H. Carpenter, of Dublin University, under the auspices of the Governors of the Leathersellers' Company's Technical College, at the Leathersellers' Hall, St. Helen's Place, Bishopsgate, E.C.3. It will be remembered (SUPPLEMENT, October 28th, 1922, p. 161) that the British Medical Association has appointed representatives to take part in a conference with the object of petitioning the Board of Agriculture to make it compulsory for farmers to take steps to eradicate this pest. Professor Carpenter will outline the work that the Warble Fly Committee has carried out, and his lecture will be illustrated by lantern slides showing the various experiments that were conducted. Medical practitioners who are interested in the subject are invited to be present at the lecture.

MEDICAL MEMBERS OF THE NEW PARLIAMENT.

The following medical men who sat in the last Parliament have been returned to the House of Commons:

- Dr. WALTER E. ELLIOT (U.), Lanark. Majority 2,193 on a total poll of 21,817.
 Dr. F. E. FREMANTLE (U.), St. Albans. Majority 3,932 on a total poll of 25,256.
 Dr. J. E. MOLSON (U.), Gainsborough. Majority 1,799 on a total poll of 21,115.
 Sir WILLIAM WHITLA (U.), Queen's University, Belfast; returned unopposed.

To the above names may be added those of two medical men who have previously sat in the House of Commons:

- Dr. W. A. CHAPPLE (L.), Dumfries. Majority 2,241 on a total poll of 24,351. (Dr. Chapple formerly sat for Stirlingshire.)
 Mr. C. HARVEY-DIXON (U.), Rutland and Stamford. Majority 3,042 on a total poll of 21,985. (Mr. Harvey-Dixon has, we understand, long retired from practice.)

New Members.

The following members of the medical profession have been elected to Parliament for the first time:

- Sir GEORGE A. BERRY (C.), Combined Scottish Universities. Returned unopposed in succession to Sir Watson Cheyne, as joint Member with Sir Henry Craik and Mr. Cowan.

Sir George Berry, LL.D., is honorary surgeon-oculist to the King in Scotland and consulting ophthalmic surgeon to the Edinburgh Royal Infirmary; he has been President of the Royal College of Surgeons of Edinburgh and of the Ophthalmological Society of the United Kingdom.

- Sir JOHN COLLIE (Nat. Lib.), Glasgow, Partick. Majority 5,472 on a total poll of 18,036.

Sir John Collie, C.M.G., M.D., was formerly Director of Medical Services at the Ministry of Pensions and president of the Special Medical Board for Neurasthenia. He is medical examiner to the London County Council and chief medical officer of the Metropolitan Water Board.

- Dr. L. G. S. MOLLOY, D.S.O. (U.), Blackpool. Majority 165 on a total poll of 36,246.

Dr. Molloy is honorary consulting physician to the Victoria Hospital, Blackpool. During the war he served in France and Flanders as major in the Duke of Lancaster's Own Yeomanry; he was twice mentioned in dispatches and awarded the D.S.O.

- Sir SYDNEY RUSSELL WELLS, University of London. Majority 1,653 on a total poll of 7,440.

Sir S. Russell Wells, M.D., is physician to the Seamen's Hospital, Greenwich, and the National Hospital for Diseases of the Heart. He was Vice-Chancellor of the University of London from 1919 to 1922.

- Dr. A. SALTER (Lab.), Bormondsey West. Majority 2,325 on a total poll of 16,917.

Dr. Alfred Salter is the senior partner in a large practice in South London, and has taken a prominent part in social work and local politics. He is a distinguished student of Guy's Hospital and a gold medalist of London University.

- Dr. T. WATTS (U.), Withington. Majority 670 on a total poll of 22,686.

Dr. Thomas Watts is a past chairman of the Ashton-under-Lyne Division of the British Medical Association, and has been president of the Association of Certifying Factory Surgeons. He practised for many years at Hyde, Cheshire, where he was a member of the Town Council.

- Dr. J. H. WILLIAMS (Lab.), Llanelli. Majority 7,266 on a total poll of 39,160.

Dr. John Henry Williams, J.P., is in practice at Barry Port, Carmarthenshire. He is a member of the Carmarthenshire County Council and chairman of the Health Committee.

Five medical men who sat in the last Parliament did not seek re-election—namely, Sir Watson Cheyne, Dr. A. C. Farquharson, Dr. Nathan Raw, Dr. P. F. B. Macdonald, and Sir Robert Woods. The last-named was one of the representatives of Dublin University, which under the Home Rule Act no longer returns members to the British Parliament. Two medical men who were in the last Parliament were defeated at the polls—namely, the Right Hon. Christopher Addison, who sat for Shoreditch, and Dr. Murray, who was member for the Western Isles.

Mr. Whitley was re-elected Speaker on November 20th, and on the following day members came up in line at the table in the Commons to take the oath and subscribe the roll, preliminary to the State opening of Parliament by the King on Thursday.

RADIOLOGY AND ELECTROTHERAPY.

JOINT MEETING IN MANCHESTER.

A joint meeting of the Röntgen Society and the Electrotherapeutic Section of the Royal Society of Medicine was held on November 17th and 18th in Manchester. At the opening of the proceedings in the Physics Department of the University, Dr. ROBERT KNOX, President of the Electrotherapeutic Section, who was in the chair, said that this was the first visit of the combined societies to the provinces, and expressed the pleasure the London members had in visiting Manchester.

The Structure of Metals as Analysed by X rays.

Professor W. L. BRAGG, F.R.S., who read a paper on this subject, said that the x-ray analysis of metallic structures opened up an entirely new field of research. Just as chemical analysis told the nature and properties of the constituent elements which went to build up a complex substance, so this new type of "physical analysis" told what crystalline solids were present in a substance and how the atoms in these solids were arranged relatively to each other. Much of the pioneer work in this region had already been done, for the structures of most of the pure metals had been ascertained, but the modifications of metallic properties due to the admixture of other elements were of vast interest to the metallurgist and engineer. An indication of what might be done in this direction was afforded by Westgren's work on the irons and steels. The metallic structures could be elucidated, the effect of dissolved impurities studied, admixture of other phases recognized, coefficients of temperature expansion accurately measured, and the size of crystalline grains determined when these were of colloidal dimensions. It was of the greatest importance that the possibilities of this new method of analysis should be recognized, and research workers trained in its technique. Mr. W. J. WILSHIRE, of the Research Department, Woolwich Arsenal, said that during the last year or so x-ray examination had been applied commercially in various directions, but there were many other possible applications, even at the present stage of development. He discussed various practical points in the use of x rays for non-medical purposes. The effect of "scattering," particularly in the photographic plate itself, was dealt with, and also points in the rendering of fine detail in a metal radiograph, and the gauging of correct exposures from absorption curves. The conditions for visual work with the fluorescent screen and the possibility of detecting small flaws with the screen were discussed. Slides were shown of a portable factory x-ray apparatus, and also a method of rapid radiographic examination of large quantities of a particular article at the rate of 2,000 a day, designed in the research department at Woolwich Arsenal. Other x-ray applications were the accurate measurement (to 1/1000 inch) of hidden components, and also the rapid estimation of the lead content of brass or other alloys.

The Hot Wire Sphygmograph and the Psycho-galvanic Reflex.

Professor A. V. HILL demonstrated the "hot wire sphygmograph" and the "psycho-galvanic reflex." The former, he said, recorded on a string galvanometer the change of electrical resistance of a fine platinum wire suddenly cooled by a puff of air. The record was valuable in studying the time relations of mechanical events occurring in the body, and particularly in measuring the velocity of the pulse wave and therewith the elasticity of the arteries in man. The latter was a vivid physical expression of involuntary bodily reactions to emotion or changes of "attention"; it consisted merely in an alteration of electrical resistance (or rather of polarization) set up through the agency of the involuntary nervous system.

Storage Batteries.

Mr. E. C. McKINNON, A.M.I.E.E., said that during the last thirty-five years a great amount of attention had been devoted by engineers, scientists, chemists, and inventors to the production of storage batteries for use in science and commerce. They had played a most important part in the great war; the submarine, for example, would be innocuous without storage batteries. Millions of such batteries were made annually for innumerable purposes; the world consumption of lead in their construction amounted to many thousand tons a year, and the number of persons engaged in the industry was estimated at from 100,000 to 150,000. Any real advance in the art must

be looked for from scientifically trained men engaged in technical research, and completely conversant with commercial conditions. Performance in laboratories bore little relation to performance under service conditions. Competition had tended to crush out any refinements which increased cost of manufacture and upkeep, and to reduce the products to a common standard. Standardization also had wiped out many anomalies. The standard battery was a compromise of the factors—capacity, weight, bulk, and durability. Scientific management was necessary to obtain the best results from a battery; a fool-proof battery appeared to be impracticable. Mr. McKinnon detailed some of the technical essentials in storage battery manufacture, and concluded by demonstrating numerous types of batteries and their component parts.

Measurement of High Voltages.

Mr. J. R. CLARKE, M.Sc., said that the methods of measuring high voltages which only gave mean values were not much use to the radiologist, who was chiefly concerned with the peak value of the wave he used. Hitherto the peak value had usually been measured by the spark-gap, though other methods involving condensers, rectifiers, and similar apparatus had been employed. The latter required careful attention in order to obtain good results, and the spark-gap could not be continuously in parallel with the tube. The utilization of the corona in air from a wire surrounded by a coaxial cylinder was suggested. Corona commenced when there was a definite potential difference between the wire and cylinder, depending only on their radii and the density of the air. Such an arrangement could be connected in parallel with the x-ray tube, and the corona current between wire and cylinder could be detected either by a galvanometer or telephone. The voltage applied to the tube could thus be measured by observing the conditions under which corona occurred. If the radii were suitably chosen there was extremely little tendency for sparks to pass between the wire and cylinders. By regulating the radii and the density of the air so that the corona just should not occur no power was consumed in the voltmeter and it could be operated continuously in parallel with the tube. The corona current might be amplified if desired, to act as a control by means of which the voltage in the high tension circuit could be maintained at a constant value.

Canterization of Pleural Adhesions under Thoracoscopic Control.

At the Royal Infirmary, in the afternoon, Dr. H. C. JACOBÆUS, Professor of Medicine in the University of Stockholm, gave an address before a large audience on the canterization of pleural adhesions under thoracoscopic and x-ray control. He said that for ten years he had been using the endoscope in studying the peritoneal and pleural cavities. At first he had been concerned only with the diagnostic advantages of the method, and used it chiefly in cases with ascites. After replacing the ascitic fluid with air he was able to obtain a clear and comprehensive picture of the abdominal organs. Later on he combined this laparoscopy with the simultaneous x-ray examination of the abdominal organs after introduction of air. The most interesting application of the method was for the examination of the pleural cavity; it was so simple and direct that it could be performed without inconvenience in any case of pleurisy with effusion in which thoracocentesis could be done. After sufficient practice it was possible to distinguish with some certainty between tumour metastases and tuberculous changes. In doubtful cases it was possible to determine the nature of the pleurisy by making an excision under guidance of the thoracoscope. In cases of pulmonary tuberculosis subjected to the pneumothorax treatment a clear picture could be obtained with the thoracoscope of string-like or membranous-like adhesions which might exist, and, by attaching the lung to the thoracic wall, prevent it from collapsing and thus cause the pneumothorax treatment to be a failure. He had devised a method of severing such adhesions with the galvano-cantery. Local anaesthesia was used in almost all cases, and the thoracoscope was introduced through the back. The selection of the point at which to introduce the galvano-cantery to sever the adhesions was of great importance. As in most cases adhesions were high up and to the side, he as a rule introduced the galvano-cantery in the antero-axillary line in the seventh, eighth, or ninth intercostal space. If necessary the cantery could be introduced still higher up, in the axillary line; if the adhesions were near the diaphragm the cantery might

be introduced in the lower part of the thoracic wall. The application of the platinum needlo of the galvano-cantery was made under the guidance of the thoracoscope. To obviate the risk of hæmorrhage the needle was kept at a slight glow.

Among the complications which might occur after the operation was emphysema of the skin, originating from the puncture, but it caused trouble only for a day or two. More important were the pleuritic exudates which might develop after the operation, as shown by the following table:

Without exudate	35
With slight exudate	19
Long lasting exudate and fever	11
Long lasting exudate and fever, accompanied by empyema	7*
Exudate appearing only one to three months after operation	2
				75

* Of the 7 cases of empyema 4 died, 1 soon after operation.

Of the first 78 cases reported, in 55, or about 75 per cent., the method was technically successful in removing adhesions which had prevented the complete collapse of the lung. The clinical results were not so favourable, as only 49 cases, or about 65 per cent., had been freed from symptoms. The following table shows the results in 103 cases from various sources:

Results of Canterization.

Jacobæus.	No. of Cases.	Canterization Complete, or Sufficient for Collapse of Lung.	Good Clinical Result.	Incomplete Canterization.
Apical adhesions ...	10	9	8	1
Lateral adhesions ...	62	45	41	17
Diaphragmatic adhesions...	3	3	1	—
Total ...	75	57	50	18
Holmboe ..	12	7	7	5
Gravesen (Saugmann) ..	16	9	7	7
Total ...	103	73	64	20

Dr. Jacobæus then passed on to consider certain cases of tumour operated upon by Dr. Key after examination by the x rays and the thoracoscope. His general conclusions were that an x-ray examination, both before and after the induction of pneumothorax, was of great importance in the diagnosis and localization of pleural and pulmonary tumours, and that thoracoscopic examination gave valuable information in the diagnosis and localization of such tumours, and verified the x-ray examination. Where it was not possible to use a pressure-difference apparatus it might be advantageous to induce pneumothorax previous to operation in the pleural cavity. If a pressure apparatus were employed then pneumothorax for the thoracoscopic examination ought to be induced as shortly before the operation as possible, in order that the inflation of the lung after the operation might not be rendered impossible. If the lung was inflated after the operation more favourable conditions for healing were eventually obtained.

Sir HUMPHRY ROLLESTON, K.C.B., M.D., President of the Röntgen Society, who was in the chair, in proposing a vote of thanks, said that the work Professor Jacobæus had done on this subject broke new ground which required a good deal of thought. Professor G. R. MURRAY spoke of the treatment of pulmonary tuberculosis by artificial pneumothorax, and of the work of Professor Jacobæus as being definite advance. Professor A. H. BURGESS discussed the technique of the operation, and favourably compared the method of Professor Jacobæus by canterization under thoracoscopic control with division of pleural adhesions by the knife under x-ray control.

Dr. MARSSEN said that, though he was not an enthusiastic supporter of the method of treating pulmonary tuberculosis by artificial pneumothorax, he thought some of the failures might be due to the presence of adhesions preventing full collapse of the lung.

Mr. THURSTAN HOLLAND, speaking as a radiologist, praised the series of beautiful radiographs shown by Professor Jacobaeus, and advanced as a reason for the failure of artificial pneumothorax the fact that it was too often done in this country without proper radiographic control.

MANCHESTER ROYAL INFIRMARY.

Opening of the New X-Ray Department.

On the evening of Saturday, November 18th, the new x-ray department of the Manchester Royal Infirmary was opened by Sir Humphry Rolleston. The proceedings were presided over by Sir WILLIAM CONNERT, chairman of the Board of Management. In his opening remarks the chairman referred to the gift by Mr. Robert McDougall of £5,000 for the equipment of the new department in memory of his father, Mr. Arthur McDougall, B.Sc.; also to an anonymous gift of £4,000 for the intensive x-ray treatment equipment and the provision of a research scholarship in this method of treating cancer. Dr. A. E. BARCLAY, senior honorary radiologist, explained the organization of the department, with lantern slide illustrations. Mr. McDougall responded to the expression of thanks conveyed by the chairman, and Sir WILLIAM MILLIGAN, M.D., chairman of the Research Committee, replied on behalf of the anonymous donor.

Sir Humphry Rolleston's Address.

In the course of his address Sir HUMPHRY ROLLESTON expressed admiration for the splendid x-ray department now possessed by the Royal Infirmary, and his pleasure at having that opportunity of seeing what Manchester was doing to-day in one of the most progressive branches of the science and art of medicine. The finished product prompted him to glance briefly at the history of the development of radiology in connexion with that institution since the early days of the application of Röntgen's discovery to medicine. At first the practical utility of x-rays appeared so problematic that even so finely conceived an institution as the new Manchester Royal Infirmary was planned without provision for a department, and it was not till 1908 that a small room in the basement was formally assigned to the work. The Royal Infirmary was to be congratulated on the patient enthusiasm of Dr. Barclay, who had done so much for its reputation by working up the organization of this department; his great services were recognized by his appointment in 1918 as a member of the honorary staff.

Sir Humphry Rolleston continued:

It is most important that there should be the closest co-operation and communication between the workers in the wards on the one hand and those in the laboratories and radiological department on the other hand. Without such team work and the resulting sympathetic insight into the mutual aims, difficulties, and limitations of these two classes of workers the progress of medicine must suffer and be delayed. Wisely recognizing this essential condition for success those responsible for the construction of this x-ray department have provided a large demonstration room with a big x-ray and screening apparatus, so that patients can be brought down and examined by the radiologist and the physician or surgeon and the attendant students. In addition a lantern is provided for the demonstration of slides from similar cases to that under discussion, so that light may be thrown on any unusual features in these cases. There will thus be available a collection of negatives and slides—comparable to a museum of pathological specimens—which will become more numerous and so more progressively valuable for teaching and research in medicine and surgery. Team work between radiology and the other branches of medicine may be confidently expected to bear much fruit in research and the advancement of medical science, diagnosis, and treatment. In the case of the Manchester Royal Infirmary the omens in this respect are specially propitious, for not only has Dr. A. E. Barclay an international reputation for original investigation, especially as regards the gastro-intestinal tract, but a generous benefactor who prefers to remain anonymous has provided £4,000 for research in connexion with the intensive x-ray treatment initiated at Erlangen, and a strong committee has been set up consisting of Sir William Milligan, Professor Bragg, Professor H. R. Dean, Dr. C. Powell White, Dr. A. E. Barclay, Dr. A. Burrows (of the Manchester Radium Institute), and James Watt, junr.; in May, 1921, Dr. C. C. Anderson was appointed Research Scholar and worked in Germany from July, 1921, to January, 1922. The combination of radiology and anatomy has greatly advanced our knowledge and efficiency in both these subjects; radiology has thrown a flood of new light on normal anatomy, especially of the abdomen; in this field of advance Dr. J. S. B. Stopford, professor of anatomy here, is the pioneer; and it is most appropriate that Dr. J. M. W. Morrison was in 1921 appointed lecturer in applied anatomy (radiology) in the University of Manchester. It is obvious that a knowledge of the normal x-ray appearances and of their physiological variations is fundamental in the estimation of morbid

changes and in the detection of disease, and on this subject there still remains much to be done. Team work with pathologists offers an attractive field for investigation; the x-ray examination of bodies before *post-mortem* examination, originally practised by Dr. F. H. Williams, of Boston, Mass., in 1906, and found to be of great value in the diagnosis of the thoracic complications of virulent influenza in 1918-19 (H. B. Robertson), is a perennial source of information. Possibly, by combined investigations with pathological workers, the severe reactions of a toxic nature that may follow intensive radiations, and are a serious factor in the utilization of the method, may be found, as Aub and Witherbee's experimental work on rabbits suggests, to be preventable by increasing the resistance of the normal cells of the body by some procedure such as the injection of horse serum.

Sir Humphry Rolleston then spoke of the vigorous growth of the art and science of radiology, and the vast increase that this had led to in the demands made on the radiological department. The whole subject, he said, was rapidly expanding and advancing, so that in the near future it would be necessary elsewhere, as had already been done in Manchester, to provide a university hospital with several radiologists, each specializing in a branch of the subject.

The vote of thanks to Sir Humphry Rolleston was proposed by Dr. RAMSPORRION, Chairman of the Medical Board. The new department was visited during the afternoon by the members of the two societies. The main features of the department are briefly:

1. Its complete equipment for all kinds of x-ray work, both diagnostic and therapeutic.
2. The extensive and well-ventilated premises.
3. The efficient protection of the workers by the use of barium plaster on the walls.
4. A well-fitted workshop in which minor repairs can be done and experimental apparatus made.
5. A demonstration room fully equipped for the exhibition of cases and the teaching of radiology to students.

DINNER.

A dinner was held at the Midland Hotel at 7.30 p.m. About eighty members and friends were present, including the presidents of the two societies. The guest of the evening was Professor Jacobaeus, whose health was eloquently proposed by Dr. R. Knox. Later on several speakers referred to the value of co-operation between physicists, manufacturers, and radiologists. Sir ARCHIBALD REID outlined a scheme for a British Institute of Radiology which it is proposed to establish in London. The proceedings terminated with various votes of thanks to those who were responsible for the successful arrangements in connexion with the conference.

VISITS.

On Saturday morning opportunities were afforded for visits to various works, including the Chloride Electrical Works, which make storage batteries. Visits were also paid by the medical members of the meeting to the Radium Institute and to the x-ray department of the Skin Hospital.

Scotland.

THE SAMSON GEMMELL BEQUESTS.

THE late Dr. Samson Gemmell, admired and beloved by many generations of Glasgow students, and for five or six years before his death in 1913 Regius Professor of Medicine in the University, left a considerable fortune, which passed to his only brother, Mr. William Gemmell. He died recently, and by his will bequeathed his estate, which it is believed will amount to about £100,000, for the benefit of Glasgow institutions. He left £20,000 to trustees for the purpose of establishing a chair in the faculty of medicine or science, to be called the Samson Gemmell chair. The trustees are to confer with the University authorities as to the subject of the chair and the arrangements for the appointment. The trustees are to hold the remainder of the estate as a permanent Gemmell Bequest Fund; its income is to be applied to charities in Glasgow, and mention is made also of charities in the parish of Sorn, Ayrshire, from which place the Gemmell family came.

CENTRAL MIDWIVES BOARD FOR SCOTLAND.

The examination of the Central Midwives Board held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, concluded on November 8th with the following results: Out of 116 candidates who appeared for the examination 99 passed. Of the successful candidates 21 were trained at the Royal Maternity Hospital, Edinburgh, 37 at the Royal Maternity

Hospital, Glasgow, 3 at the Maternity Hospital, Aberdeen, 11 at the Maternity Hospital, Dundee, 7 at the Queen Victoria Jubilee Institute, Edinburgh, 11 at the Cottage Nurses' Training Home, Govan, Glasgow, and the remainder at various recognized institutions.

GLASGOW MEDICAL LUNCH CLUB.

At the meeting of this club held on November 16th the vice-president, Dr. John Henderson, occupied the chair, the guest of honour being Sir William Martin. After lunch Sir William Martin gave a very interesting and illuminating account of the inception and development of the Royal National Lifeboat Institution, and its increasing value to the country. He emphasized that all along it has been supported by voluntary subscription, without any aid or subsidy from the State. The lecturer illustrated his remarks with many important figures, financial and otherwise, indicative of the valuable work done by the institution for the nation. The address was thoroughly enjoyed, and the pleasure and thanks of the members were suitably expressed by Dr. McKail. He referred to the untiring efforts of Sir William Martin in the advancement of the lifeboat cause locally and generally, as, for many years past, organized public collections had been made on an appointed day, and that to these was due the inception of "flag" days, which had proved so valuable in swelling the funds of so many deserving objects all over the country.

Ireland.

PRESENTATION TO DR. M. F. COX.

On the occasion of his election to be president of the Royal College of Physicians of Ireland, Dr. Michael F. Cox, senior Physician to St. Vincent's Hospital, was presented on Saturday, November 11th, with a beautiful replica of the Ardagh Cup by his colleagues in the hospital. The presentation was made at a complimentary luncheon to Dr. Cox in the Shelbourne Hotel. Surgeon McArdle, who presided, in making the presentation, said that it was a small recognition of life-long work and of the affection and respect with which his colleagues in the profession, as well as in the hospital, regarded him. The honour of being elected President of the College of Physicians was long overdue. As far as his memory went back Dr. Cox had carried himself first of all as a brilliant Irishman, and secondly as a staunch Irishman. There were brilliant Irishmen, he might remark, who were of no use to their country, but the man who combined staunchness and brilliance rightly won their highest appreciation. Throughout his life Dr. Cox had been continuously straightforward with everyone who met him and always true to the poor. He had known him for thirty years and could say that no other man he knew had been so invariably considerate. His loyalty to his hospital was a model for physicians. Surgeon McArdle then proposed the toast of Dr. Cox, a friend of the poor, a patriotic Irishman, and an honour to his profession. After the toast had been duly honoured, Mr. John Dillon, ex-M.P., and a Licentiate of the Royal College of Surgeons in Ireland, thanked the organizers for the opportunity to pay a brief tribute to his old friend, Dr. Cox. Since they had been students together they had remained on terms of the closest intimacy. He did not think there was another physician in Dublin who had been so uniformly and meticulously kind to the poor, or a more steadfast and generous friend. He had steered a straight and honest course through life, and his reward was that there was not a man in the medical profession to-day who was more beloved by the people of Dublin. Dr. Cox, in reply, thanked his friends for their very great kindness; they made him feel very proud and happy, for he realized the generosity which prompted their action. St. Vincent's Hospital and the good sisters were beloved by them all, and he thought he could say that a better staff was possessed by no hospital. He thanked them from the bottom of his heart collectively and individually. The Right Hon. Thomas O'Shaughnessy, Recorder of Dublin, proposed the toast of the Chairman, which was duly honoured.

MR. ANDREW FULLERTON.

Mr. Andrew Fullerton, O.B., C.M.G., F.R.C.S.I., surgeon to the Royal Victoria Hospital, Belfast, read a paper on unilateral diuresis at the Congress of the American College of Surgeons in Boston, which began on October 23rd and

terminated on October 28th. He also gave an address before the Toronto Academy of Medicine, and spoke at the Mayo Clinic, Rochester. Since his return to Belfast he has received many congratulations on his election to the honorary Fellowship of the American College of Surgeons. He is the first surgeon in the North of Ireland to receive this distinction.

SMALL-POX MENACE.

In view of the outbreak of small-pox in England, precautions are being taken to prevent the introduction of the disease through the port of Dublin. Incoming vessels are thoroughly inspected, and the slightest case of illness on board is reported to the Port Medical Officer. Where any doubt exists, no member of the crew is allowed ashore until the medical officer is satisfied that all risk is removed. Owing to the possibility of infection from second-hand clothing, the acting Port Medical Officer (Dr. M. J. Russell) has instructed the Port Sanitary Inspector to prevent the importation of such articles, and the various shipping companies have expressed their readiness to give immediate information of the arrival of such goods, with a view to disinfection. Dr. Russell reports that during October no case of infectious disease was reported from, or detected in, any vessel which had entered the port; twenty-five foreign vessels were inspected, and fourteen notices were served requiring the keeping of rat guards on the mooring ropes, as a precaution against disease being carried ashore. During the week the Dublin Board of Guardians passed the following resolution by a majority of one:

That owing to the danger of an outbreak of small-pox in Dublin, the following resolution, passed by the Board on August 4th, 1920: "That it be optional for parents to have children vaccinated," be, and is hereby, rescinded, and that the Board give instructions to have the Vaccination Regulations carried out.

Correspondence.

SMALL-POX DIAGNOSIS.

SIR,—Will you permit me to submit to your readers some observations on this topic which are of urgent professional, and public, importance?

An actual occurrence may give point to my remarks. The first of the 10,000 cases certified as small-pox which I saw in 1901-03 was that of a girl child of a litigious mother, who brought an action for damages against her physician, a competent and careful practitioner, in that he had certified her child to be suffering from small-pox when, in fact, she was suffering from chicken-pox, and by his negligence had ruined the mother's business. The case hung over his head for more than a year, and but for being most ably defended by the Medical Defence Union would, probably have caused him severe loss. Before my evidence was called the case was stopped by the jury, who by then were satisfied in effect (a) that the physician had taken every care to render himself competent in the branch of medicine in which he was practising and was so competent, (b) that on this particular occasion he had taken all due and reasonable care. He had done his best, and no man could be asked for more. The verdict was for the defendant.

That was in 1901. What of 1922? We all know that "missed" cases continue to occur, but in my experience they are much fewer than they used to be; and it makes me exceedingly proud of our profession to find, as I have found on three occasions lately, that colleagues who previously had never seen a case of small-pox had recognized the disease on the first day of the rash. That is an achievement of high merit and shows what can be done by junior men, even though the majority of physicians have never seen a case of small-pox—for the simple reason that there have been none to see.

All the same, cases are still missed, being taken for measles, or chicken-pox, or a drug rash, or scarlet fever, or influenza; and such occurrences lead to a sequel of five, ten, fifteen, or more deaths as the case may be.

Those of us, however, who have seen much small-pox know exceedingly well that many cases present remarkable difficulty in recognition; the majority of the recent London cases have been far from straightforward; this phenomenon has not been due to their vaccinal condition, which, contrary to the experience of Dr. Killick Millard, I have found rather facilitates than obscures the diagnosis, but more often to

a commonly overlooked factor—namely, the specific skin texture and constitution of the individual patient; and anyone who vividly recalls his own early efforts successfully to tackle this most formidable enemy—for myself that was in the early nineties—can have nothing but profound sympathy for the stress and anxiety often thrown on members of our profession. It was this consideration which greatly influenced me in producing my various works on small-pox. I have constantly done all I could to coach my colleagues therein, or at least to place this knowledge easily within their reach. It has been, one might almost say, a labour of love, has occupied my leisure during year after year, and I suppose has cost me not less than £500 of my private means. I find no mention whatever of these rudiments of small-pox diagnosis in leading textbooks of medicine, though the pregnant work of the late Dr. T. F. Rickotts has been before the profession for over twenty years and has been proved by many physicians to be of priceless value; yet many of my medical friends have no idea where to light upon this to them recalcitrant work. Complaint I have none; I only deplore the deficiency in my own powers of persuasion, which I am now attempting to remedy. May I venture to digress here in order to request for future work the loan of any striking small-pox photographs in the possession of your readers, especially if they should have photographs of any of the Poplar or other recent severe cases.

What I am more especially concerned with now is that I am not immortal, and it has always seemed to me one of the real tragedies of existence that a stone of experience which some Sisyphus has rolled up a particular hill should roll down again unheeded at his death; in brief I wish to do all I possibly can to make this invaluable knowledge more widely available. I have done nearly all I can do in this matter, and by way of removing any suspicion of personal advantage—there never was any—I have for some years now been in the habit of placing any surplus over cost of the production of my work towards a special fund for the general furtherance of this knowledge. If you or any of your readers can suggest a more suitable basis I will gladly consider it.

What I do most earnestly seek at this juncture, when the external pressure of small-pox infection seems higher than for twenty years, when the susceptibility of our population, largely owing to non-vaccination, seems also higher than for a long time past, when a single "missed" case may involve us all in a huge disaster, and when in consequence the utmost possible medical vigilance on the part of us all is necessary to tide us over a critical period of great anxiety until the time when the common sense of our people asserts itself (as I rejoice to say it is slowly asserting itself) and voluntary vaccination becomes the rule and finally saves the situation—at such a time I do beg to be allowed to tender to my colleagues whatever assistance of this nature may be convenient to them and in my own power.

In my daily experience I note that the laity themselves are much more educated and alert upon this question than twenty years ago, and in several obscure cases lately the correct diagnosis has been first suggested by the patient. Many laymen are at least cognizant of the marked advance which medical research has made in small-pox diagnosis in this twenty years. It is indeed as striking an advance as any in surgery or medicine. That young practitioners who have never seen a single case should be able to make a correct diagnosis of small-pox on the first day of the rash is indeed a portent; and I surmise that if again one of us finds himself arraigned in the courts by an infuriated patient for having ruined his business by a misdiagnosis, the question will probably be asked by the court what steps the defendant has taken to familiarize himself with recent diagnostic methods, and the verdict will be influenced thereby.

Lectures have been given at several of the London general hospitals, and at one of them the question is understood to be under consideration whether it is desirable to require that applicants for house appointments should have attended a short course of instruction upon the subject. It is to be hoped that this admirable example will come to maturity and be widely followed.

May I, Sir, in thanking you and your readers for your kind attention, submit that the very key of our success in holding this invader in check is instant recognition, and is the very key, too, of success in that ultimate objective upon which we are

obstinately determined—namely, the summary expulsion of this pest from among us and the complete security of our island from its loathsome interference for all time to come.—I am, etc.,

London, S.E.1, Nov. 17th.

W. McC. WANKLYN.

P.S.—I append a list of publications which may be obtained from the *Medical Officer*, 26, Whitefriars Street, E.C., and from George Wareham, 1, Bridge Row, Cannon Street, E.C.: "How to Diagnose Small-pox" (5s.). "Small-pox Notes for Medical Practitioners, with Hints on Small-pox Diagnosis" (6d.). "A Survey of the Present Position of Small-pox and Vaccination as Affecting this Country" (1s.).

THE OUTBREAK OF SMALL-POX AT POPLAR WORKHOUSE.

Sir,—I gather from Dr. Killick Millard's letter (November 18th, p. 1001) that in 1911 some 70 cases of small-pox (with 10 deaths) arose at Mile End, following upon the occurrence of an "overlooked" case of a girl of 12, who had been vaccinated. Dr. Millard says that the press emphasized the neglect of vaccination as a cause of the outbreak, but did not mention that the first case, a girl of 12, had been vaccinated. Dr. Millard is "fairly confident" that a vaccinated case, presenting a modified attack of small-pox, was the cause of the present outbreak.

I deduce from Dr. Millard's letter that it would be better to stop vaccinating, so that when the first case occurs, this being unvaccinated, it could be readily diagnosed, and then would be the time to vaccinate contacts. If this be Dr. Millard's view, I say that it is dangerous, fallacious, and, if adopted, would lead to widespread epidemics of small-pox.

Dr. Millard's unmodified first case, in actual practice, would not be likely to oblige by walking right into the arms of a medical man. More than likely the sufferer would have visited forty or fifty public houses, churches, or cinemas, and, it may be, would have danced at a night club or have attended a meeting of the society for the propagation of contraceptives, amongst the heathen (home mission scheme). In this manner the heather would soon be set on fire.

As the crow flies, we in Deptford are not more than three miles from Poplar, and quite naturally there has been an element of expectancy—nay, indeed, strain. With so many unvaccinated people going about, and with a vaccination campaign (and a successful one) on hand in Deptford, Dr. Millard's theorizing is irritating, and might be injurious. At our Council meeting a week ago, when chicken-pox was made notifiable *pro tem*, an alldorman expressed views unfavourable to vaccination, and referred to "eminent medical men" who were against it.

The *BRITISH MEDICAL JOURNAL* is freely quoted by the press, and who knows but what this "beavered haro" that has been let loose upon an unsuspecting public from the Leicester Public Health Department may be quoted with disconcerting results? Let us have vaccination in infancy, revaccination at 12 to 14, and a third session at 21, with additional interviews with the scarifier as and when necessary. With such sound and convincing practice we would not need to let our hearts be troubled with the "shimmy shake" ideas we are asked to believe.—I am, etc.,

CHARLES S. THOMSON,
Medical Officer of Health.

Town Hall, Deptford, S.E.14, Nov. 18th.

Sir,—Dr. C. Killick Millard may or may not be correct in his supposition that "the patient whose overlooked attack is responsible for the outbreak" of small-pox at Poplar was a vaccinated person. Assuming, however, that his "confident surmise" is correct, it would be interesting to know what he proposes to do about it. The logical sequel of his letter would appear to be the suggestion that vaccination should be made a criminal offence. In this he might be supported by Mr. Arnold Lupton and Dr. Walter Hadwen, although in justice to these gentlemen I must say I am not aware that they have ever openly advocated such a course. I fear it would be but small consolation to the friends of a person who had died of virulent small-pox that there was no difficulty in the diagnosis of his disease. There would still be mild cases of small-pox, just as there are mild cases of scarlet fever and measles which are sometimes difficult of diagnosis. Even now severe cases are sometimes overlooked. I was recently in the company of an eminent surgeon, who, when a house-surgeon forty years ago, had been for eight weeks or so shut up in a

ward of a general hospital along with a small-pox patient who had been admitted under the diagnosis of "pustular eczema." I grant that there would probably be *relatively* fewer mistakes in diagnosis, because every medical man, and perhaps most others, would be only too familiar with small-pox, whereas now hundreds of medical men have never seen a case. It is possible, however, to pay too dearly for the education of medical men and the public in the diagnosis of small-pox.—I am, etc.,

Reading, Nov. 20th.

F. W. STANSFIELD, M.D., D.P.H.

CANCER OF THE SCROTUM.

SIR,—The article by Messrs. A. H. Southam and S. R. Wilson in the *JOURNAL* of November 18th (p. 971) is of great interest. They attribute to the lubricating oils used in the cotton mills of South Lancashire the property of inducing cancer of the scrotum in mule-spinners, and they announce their intention of investigating the question experimentally.

Though it has long been known that the crude mother liquids from which lubricating oils are prepared predispose to, if they do not actually produce, cancers in the workmen engaged in the refineries, yet no one hitherto has recorded cases of cancer traceable to the action of lubricating oils themselves. At the Glasgow meeting of the British Medical Association in July last, in communicating the results of experiments with the crude mineral oil products, I reported the fact that I had produced malignant disease in mice with such substances. That paper will, I hope, soon appear in the *JOURNAL*, when the various papers read at the Pathological Section are printed; but may I be allowed to say, meanwhile, that I succeeded in inducing epithelioma experimentally with a lubricating oil which must be similar to, if it is not identical with, that implicated by Messrs. Southam and Wilson? It is interesting, therefore, to have such an unexpected verification from the clinical side of what I had previously shown experimentally. We are gradually working through a series of the mineral oil products used in this country.

The authors, commenting on the apparent rarity of chimney-sweepers' cancer in South Lancashire, make the same statement that other writers on the subject have made since the time of Percival Pott (1775)—namely, that the disease is becoming rarer. All the figures at our disposal show that chimney-sweepers' cancer is as common or as rare now as it ever was: there are on the average five or six cases a year in the whole of England, and in the ordinary course of things there must be instances of large general hospitals which do not have a single case for several years. The disease is, and always has been, very rare in Scotland, and it is rare in Continental countries. This is possibly due to the different coals used.—I am, etc.,

ARCHIBALD LEITCH.

Cancer Hospital Research Institute,
London, S.W., Nov. 17th.

"THE RADICAL PREVENTION OF VENEREAL DISEASES."

SIR,—I have read the correspondence that has been going on under this heading with much interest. It is obvious that if Dr. Caiger's high ideals could be reached all would be well, not only in this, but in other directions too. After 2,000 years, however, of Christian teaching there is still, as someone has said, "too much human nature in humanity." We have to face facts as they are, not as they should be. I think it is a weakness in our profession, when we discuss this subject, that we confound medicine and morals. We are doctors first, and moralists afterwards. We are too apt, in our advice to the public, to let our medical knowledge be warped by expediency and sentiment. By all means let us join those who preach continence and other high ideals; but let us first teach the means for preventing venereal disease.

The time is coming when the State must take strong action in dealing with this question. I feel strongly that Dr. Armstrong is right in his letter of November 11th in advising the notification of venereal diseases. It is the present secrecy of the consulting room and of the chemist's back parlour that encourages much of the immorality that goes on.

I am moving at the next meeting of the Health Committee of this city that the authorities be approached with a view to the inclusion of syphilis and gonorrhoea in the list of

notifiable diseases. I hope other members of the profession who are on public bodies in their various centres will do the same.—I am, etc.,

Bath, Nov. 19th.

PRESTON KING.

PREVENTION OF ANTHRAX.

SIR,—With reference to Professor Hobday's valuable paper in your issue of November 18th (p. 955)—in which he remarks, "It is time that very much sterner preventive measures were taken against it" (anthrax)—may I point out that the present unsatisfactory condition of the law is, I consider, responsible for some of the cases?

It is at present impossible for anyone contracting anthrax from a shaving brush to bring an action for damages *directly* against the responsible manufacturer or importer of the brush. If this absurd defect in the law were altered, so that the manufacture and import of anthrax-infected brushes became financially dangerous to those responsible for them, the number of cases of anthrax from infected shaving brushes would, I feel sure, quickly diminish.—I am, etc.,

Exeter, Nov. 18th.

W. GORDON.

PSYCHO-ANALYSIS.

SIR,—“A. Dreamer” in your last issue concludes his letter by saying that as he desires “to avoid an overwhelming correspondence” he adopts a pseudonym. Therein he shows his wisdom, as it is much easier to enter a correspondence column than to leave the same.

The silence in your issue of November 11th led me to think that all was over, but it was a vain hope, as Dr. McBride returned to the fray on November 18th. I am bound to reply, as I have to enter the protest that I have been misrepresented. The offending passage is:—“Ho [Dr. Steen] apparently believes that thought can occur without physiological nerve and brain activity.” I can assure your readers that I believe nothing of the sort, and furthermore I did not say so. I do not accuse Dr. McBride of wilfully misquoting me, and I fancy I understand how he made the mistake. I shall try to make my explanation as short as possible.

There are two conceptions of disorders of mind—the physiological and the psychological. In the physiological conception the assumption is that mental activity is accompanied by corresponding changes in the nervous system. The worker in this branch of study will therefore devote his attention to any alteration in the nervous system which he may observe, and he will try to discover laws which will summarize the knowledge he has gained. These laws will be expressed in physiological terms only.

The psychological conception concerns itself only with mental processes. The student here will collect mental facts, and when he has a sufficient number at his disposal will try to formulate laws, which will be stated in psychological terms only.

“It is of the utmost importance that, in the final ‘laws’ obtained by either the physiological or psychological conceptions, there should be no mixing of the terms. The physiological laws must contain no psychological terms, and the psychological laws must contain no physiological terms. Nothing but hopeless confusion can result from the mixture of ‘brain cells’ and ‘ideas.’”

Dr. Hart, from whom I am quoting, has discussed the matter with great clarity and brevity. Misconceptions are bound to arise if arguments on big subjects have to be compressed into the limits of letters. This was my main point when I wrote my first letter.

Wild horses will not drag me into a discussion of the relationship between mind and matter.

I have to thank Dr. McBride for the names of the books he recommends, one of which is well known to me. I can also assure him that I did not realize that I was being sarcastic.—I am, etc.,

City of London Mental Hospital,
Dartford, Kent, Nov. 20th.

R. H. STEEN.

THE TEACHING OF PSYCHOLOGY.

SIR,—In the Section of Neurology and Psychological Medicine at the Annual Meeting of the Association in Glasgow, the proceedings of which were published in your columns on September 23rd, 1922, a resolution was unanimously passed asking for the inclusion of the teaching of psychology and psychopathology in the medical curriculum. The urgency of the matter may be shown by the following practical considerations.

1. Dr. Stoen, in a letter in your issue of November 18th, gives some samples of cases of acute mental distress which he meets with at his out-patient department. Every experienced medical practitioner could point not only to cases such as these, which would naturally be referred to someone devoting special attention to mind ailments, but he could show that in almost every illness it is the psychical element which is responsible for the major part of human suffering. People are afraid that they are going blind, that the noises in the head indicate serious brain disease, that they are afflicted by some incurable malady, or that they are indeed "going mad." Often these fears, which may be devoid of any foundation, are kept secret lest they be laughed at; thus a vast amount of preventable suffering continues.

2. Everyone who is engaged in any sense in the practice of psychotherapy, whether or not he is technically a psychotherapist, knows that the greater number of these cases in their early stages are easily curable. On the other hand, they also know that it is only by certain methods that these troubles can be relieved. Psychic analysis is undoubtedly one of these, and we owe to Freud an unspeakable debt for the light he has thrown on the problems of the "unconscious," but I am not a psycho-analyst and therefore I will not attempt to discuss this thorny subject. My own interest in the matter lies mainly in the system of collective treatment by conscious auto suggestion which has been designed by M. Emil Coué. By this method groups of cases can be advantageously treated, and Dr. Mouier-Williams and I, who are testing this particular system, are most sanguine as to its wide utility. You have kindly referred to the small free clinic which has been established for this purpose in Chelsea, but it would be of much wider usefulness if some of the larger hospitals would allow this form of treatment to be tested in connexion with their out-patient departments.

3. Unless this matter is seriously dealt with by the leaders of the profession, the inevitable result will be another great extension of the evils of unqualified practice. The public are rapidly learning that mind treatment is necessary for the relief of suffering, and we cannot blame them for seeking help in other ways if the medical profession is not alive to their needs.

I hope that all psychotherapists will combine to press this matter upon the attention of those in authority.—I am, etc.,
London, Nov. 17th. CHARLES F. HARRFORD.

INDIRECT RESULTS OF PROSTATECTOMY.

SIR,—It is commonly supposed that the improvement which follows prostatectomy is due to renal relief by the removal of a mechanical obstruction. May I suggest that something has happened which is often of greater importance? The surgeon's attention is often drawn to cases in which there has been little urethral obstruction and no residual urine or back pressure, but in which amazing improvement has followed an operation only rendered necessary by slight hæmaturia. In such patients the prostate is often larger than many which produce obstruction. There may be no signs of renal mischief and yet the patient has been for years in lamentable health characterized by anorexia, progressive loss of weight, grave depression, irritability, incapacity for prolonged work, and very frequently that lamentable form of sexual irritability which leads to irreparable social disaster. Not unnaturally he gets classed among the acraesthenics and is thereby barred from any real prospect of relief. Such patients are the despair of physicians, who find nothing to account adequately for the condition. It seems to me that there is an explanation of these undoubted facts which has never been offered. It amounts to the definition of a new endocrine disease, which should be called "hyperprostatism." If externally the prostate secretion is powerful, and its effects, however administered, are now beginning to be recognized, it must also act as an internal secretion. But the normal gland weighs, say, half an ounce, while it may increase to ten ounces or even more when adenomatous. The morbid symptoms may be put down to the glandular secretion being itself morbid. This, however, is an unnecessary hypothesis, since oversecretion of a kind the organism is not prepared for is morbid by itself. Such oversecretion probably causes a heavy drain on the body's powers of immunization, and when these break down toxic symptoms result. It must surely be held that any glandular secretion without evolutionary work to do should be regarded as a facultative toxin. Work I am doing elsewhere strongly supports the view that any "out-of-work" secretion is a

poison. In this case, therefore, I prefer simple hyperprostatism to dysprostatism, there being no real evidence that adenomatous tissues secrete abnormally. The patient is in the position of possessing a huge abnormal accessory gland for which there are no evolutionary safeguards, and thereby occupies a position strictly analogous to that of a sufferer from hyperthyroidism.

I am allowed to say that these conclusions have met with the general approval of Dr. Langdon Brown, and also with that of Dr. G. W. Nicholson, whose work on tumours is becoming generally recognized; he considers that as a pathological entity this disease has its natural place in morbid endocrinology, while Mr. Sydney MacDonald, whose practical experience in these cases is very great, finds in such a view an explanation of observed phenomena which seemed previously inexplicable. It follows that complexes of symptoms such as those enumerated should, in the case of males in whom tuberculosis and malignancy have been negatived, lead physicians to make the tentative diagnosis of hyperprostatism and to send them to the urologist for examination. Such views will also lead the surgeon to remove non-obstructive adenomatous prostates wherever there is a characteristic but hitherto unexplained cachexia rather than merely to watch them, and to take the same course where dangerous sexual irritability is found. For it must be noted that the removal of a large non-obstructive prostate is followed in most cases by a rapid return of healthy appetite, a great increase in weight, the removal of depression, irritability, morbid sexual coithism, and incapacity for work, while the patient both looks and feels many years younger. I think it may be added that such rejuvenescence is not likely to follow so rapidly upon mere relief to renal disturbance, and therefore submit that from start to finish the drama shows every mark of progressive morbid endocrinism until a revolution is brought about by radical surgery.—I am, etc.,

London, Nov. 15th,

MORLEY ROBERTS.

BILE SALTS AND CALCIUM.

SIR,—The letter of Dr. S. Parn in the *BRITISH MEDICAL JOURNAL* of September 16th (p. 532) on the etiology of goitre gives me much cause to think. It is, however, in its bearing on tuberculosis that it has especial interest for me. All will agree that calcium deficiency plays a great part, perhaps the chief part, in tuberculosis, and I think I am right in saying that hypothyroidism is very much more common than the opposite condition. What, however, specially concerns me is his statement that bile salts aid in the absorption of calcium. I have for some time been in the habit of using bile salts and duodenal extract in the treatment of tuberculosis, as they stimulate the flow of bile and in this way probably aid in the elimination of toxins.

If bile salts directly aid in the absorption of calcium why should surgeons so fear jaundice in gall-bladder operations? Moynihan, in his work on *Abdominal Operations* (p. 620), dealing with gall bladder operations upon those suffering from chronic jaundice, referring to the diminished coagulability of the blood and the consequent danger of hæmorrhage, says: "I have never been convinced that this drug [calcium chloride] had any effect in this direction"—namely, increasing the coagulability of the blood in cases of jaundice. If bile salts favoured the absorption of calcium, surely there would be a tendency to increase coagulability of the blood when calcium was administered in a case of obstructive jaundice. But apparently it is not so.

Langdon Brown, in his *Physiological Principles of Treatment*, says (p. 8):

"Among the less known effects of iodothyron on metabolism is its influence on the liver. . . . After ligation of the bile duct the colloid in the follicles and lymphatics of the thyroid gland increases." Again (p. 330): "It is claimed that calcium deficiency may result either from defect or excess of thyroid secretion, but the usual result of thyroid excess is to increase the excretion of calcium, preventing it from being fixed in the tissues or reaching a high level in the blood."

It seems, then, to me that bile salts increase the flow of bile and thus lessen the excess of bile in the liver. The liver being relieved the thyroid has less work to do, becomes more normal, and ceases to excrete calcium.

I raise this point in no controversial spirit, but in the hope that someone with a wider knowledge of endocrinology than mine may give a better explanation.—I am, etc.,
F. E. GUNTER.

London, W., Nov. 14th.

CHOLERA OR DYSENTERY.

SIR,—I observe in your review of the War Office statistics in the *BRITISH MEDICAL JOURNAL* of October 21st a note of the "appalling" death rate of cholera in Mesopotamia—that is, over 40 per cent. Having been there in the hot weather of 1916 as a consulting surgeon I had a chance of seeing the cholera cases. During more than thirty years in the Indian Medical Service I have seen a good deal of tropical disease. I was one day asked by one of the ablest of the R.A.M.C. temporary officers to see his cholera cases. I asked him what was his death rate; he said about 45 per cent. I told him that that was good as I would expect it to be 90 under the conditions prevailing. When I saw the cases I said they were not cholera but bacillary dysentery, and advised the officer to stop milk diet, to feed the patients on dilute rice water, and to give them sufficient magnesium sulphate to get several motions daily until all mucus disappeared and the temperature was normal. I told him under no circumstances to give them opium or other drug to stop the diarrhoea as such would be fatal in a few hours.

I saw him a fortnight later and asked how his cases were doing. The reply was that he had had only one death out of many cases since he adopted the rice water and magnesium sulphate, and in the case of that one the patient complained in the night of gripes and the nurse gave him a dose of chlorodyne on her own account and he died a few hours later.

If the war statistics (medical) are no better than those of cholera in Mesopotamia it would be a good thing for posterity if they were scrapped.—I am, etc.,

HENRY SMITH, C.I.E.,
Lieut.-Col. I.M.S. (ret.).

Sidcup, Kent, Oct. 30th.

X RAYS IN HYPERTRICHOSIS OF THE FACE.

SIR,—Dr. William Mitchell's able and courageous critique of my letter to you on this subject is worthy of a better cause, for if the evidence of nearly all the living dermatologists in this country, in America, and on the Continent is to be considered at all, that cause is lost. He need but refer to the articles on the radiotherapy of hirsuties in the most modern editions of their textbooks by Sequiera, MacLeod, Whitfield, and MacKee of Columbia University, to see how overwhelming is expert opinion against the practice he advocates. The last author has minutely discussed the subject in all its bearings, including the medico-legal, and I venture to think—all ethical and other considerations apart—that as in America, so in this country, an indemnity, verbal or written, would hardly avail to protect the operator, in case of a prosecution, for ensuing disfigurement.

Dr. Mitchell has selected in support of his argument for further trial of the method the fact that "twelve years ago many leading engineers and physicists said heavier than air flying machines were impossible." He could scarcely have chosen a more trite illustration, from both his angle and mine, for in both aviation and radiotherapy there still occur disasters of a most distressing kind. This indisputable fact surely goes to confirm my view that the instrument he employs is at present too dangerous a weapon in what is after all a minor disability, for which other therapeutic measures exist.

In one respect I have to cry "touché" to Dr. Mitchell's criticism. I certainly said "too little" in the important matter of the technique used eleven and a half years ago in Sister B.'s case. I can add only one fact to the description already given—no screen was used. I gladly concede this grave error in application of the rays, but I would again emphasize the fact that no stigma appeared for three years thereafter.

I do not desire to base any argument whatever on the results in this case, which is merely cited as an incidental and contemporaneous illustration of the harm that may ensue. I am concerned here with principles only, and those enunciated by Dr. Mitchell I feel bound to condemn. Dr. Mitchell further states, in substance, that "in a number of cases of tinea tonsurans, etc.," in which permanent alopecia was accidentally caused by radiotherapy, there were no bad results as regards the skin.

To this assertion I find it particularly hard to give credence. Every single case of permanent x-ray alopecia that has passed through my hands at three general London hospitals has shown coincident or subsequent atrophy, as evidenced by wrinkling and loss of elasticity of the scalp, while not a few developed pigmentation and telangiectases as well.

It has been proved by many histological biopsies in animals that with every epilation dose (or less) to the skin a set of definite vascular and cellular disturbances occur in the epidermis, and that if these irradiations exceed a variable minimum, permanent and irretrievable damage is certain to ensue. Now the germ cell layer of the Malpighian body, and that invaginated portion of it which produces the hair shaft, are anatomically continuous, and pass insensibly the one into the other.

Is it probable that an x-ray application which causes even a temporary inhibition of hair growth and epilation can under any circumstances leave uninfluenced the equally prolific (and therefore radio-sensitive) germ cell layer of the glabrous skin, which is actually less protected by overlying tissues and nearer the anticathode than the base of a hair follicle? *A priori*, the answer should be no, and in practice the reply is given by the appearance, sooner or later, of the various stigmata already instanced.

There is a small yet important discrepancy in Dr. Mitchell's position to which attention should be called. In the fourth paragraph of his letter he writes: "In each case I warned the patients of the risks," and in his concluding sentence are the words: "... good and safe results may be obtained." Such inconsistency is a bad friend to his own convictions, and scarcely needs further comment from me.—I am, etc.,

London, W., Nov. 12th.

HENRY C. SENON, M.D.

PERIODICITY OF GNAT BITES.

SIR,—As no one has yet replied to Dr. Beddard's query as to the periodicity of gnat bites (November 11th, p. 951) I venture to offer my suggestion that the recurrent irritation may be due to the acid and alkaline wave which passes over the blood during fasting and digestion. It is well known that in certain skin troubles the irritation increases when the stomach is empty and lessens or altogether ceases after a meal. This relief has been thought to be due to the increased alkalinity or lessened acidity of the blood caused by the withdrawal of acid during gastric secretion. During this last summer I have had several very severe gnat bites, and have always noticed that the irritation was greatest immediately after getting out of bed in the mornings and not ceasing until I had broken my fast. The irritation would return as soon as the stomach was empty, to be relieved by the next meal. I judge that the severer irritation in the mornings was due to the prolonged fast during the night. Hence in my experience the irritant periodicity of gnat bites is much less than twenty-four or forty-eight hours, as stated by Dr. Beddard, and does not differ from irritant periods in other skin troubles.—I am, etc.,

Liverpool, Nov. 19th.

WILLIAM BRAMWELL.

Obituary.

G. N. BIGGS, M.B., B.S.,

Surgeon to the Ear, Nose and Throat Department, Seamen's Hospital, Greenwich, and to the Hospital for Paralysis and Epilepsy, Maida Vale.

George Nixon Biggs, M.B., B.S., Lieut.-Colonel R.A.M.C.(T.) and R.A.F., died at the age of 41 years on November 10th, 1922, after an illness lasting from August 23rd, and due to appendicitis and its complications. With his premature death the medical world of London loses a man of exceptional ability, of winning personality, and of great kindness.

The only son of Dr. M. G. Biggs of Northcote Road, S.W., for many years a member of the Council of the British Medical Association and Chairman of the Central Ethical Committee, G. N. Biggs was educated at Westminster School and St. Thomas's Hospital and in the University of Durham. On returning to London he passed through the appointments of house-surgeon to the Royal Ear Hospital and of Registrar to the Metropolitan Ear, Nose and Throat Hospital, to the honorary staffs of several London hospitals; thus he became surgeon to the Ear, Nose, and Throat departments of the Evelina Hospital for Children, the Dreadnought Hospital for Seamen, the Royal Waterloo Hospital for Children and Women, and aural surgeon to the Hospital for Nervous Diseases, Maida Vale. On his retirement from the Evelina Hospital he was honoured with appointment as consulting surgeon, although at the time a young man. As teacher in practical rhinology, laryngology, and otology in the post-graduate school at the Seamen's Hospital, Greenwich, he

carried on one of the most attractive and popular courses there; many old post-graduate students throughout the world will have very pleasant memories of his skill as an operator, his unfailing courtesy and unwearying patience in the demonstration of the work of his department.

Although the activities of his laborious hospital appointments and very busy private practice would have overwhelmed many men, Biggs's power of work was such that he was able to devote enthusiastic attention to many other sides of life. No friend ever called upon him for help without immediately securing ungrudging devotion of time and energy. In his private capacity his unselfishness, kindness, and gentle courtesy never seemed to fail. He found time to write a valuable book on *Diseases of the Ear, Nose and Throat*, articles in the *Dictionary of Practical Medicine*, and many papers in the *Archives of Otolaryngology*, the *British Medical Journal*, and the *Proceedings of the Royal Society of Medicine*.

From an early period of his life he took great interest in the R.A.M.C., and, after a service in the Volunteers that began in his student days, he joined the Territorials at their inauguration and was soon promoted to the rank of major. For some years before the war he was one of the few that regarded Lord Roberts's warnings and, foreseeing war with Germany, worked enthusiastically to improve his Territorial unit and to perfect the details of the scheme for its mobilization; for years his only holiday was taken in camp during the annual training periods. He was called up on August 3rd, 1914, as Major and Registrar for the No. 4 Territorial General Hospital and served in that capacity until Easter, 1917. He was then promoted to the rank of lieutenant-colonel and sent to France in command of the Territorial Hospital No. 54; later he was Consulting Aural Surgeon to the Boulogne district. He was mentioned in dispatches, and by the Portuguese Government was made a Commander of the Order of Luis. He was afterwards given the Territorial Decoration, and on return from France in 1918 was attached to the Medical Staff, Royal Air Force.

A man of keen enthusiasms and of lovable character, George Nixon Biggs will be greatly missed.

ROBERT MILNE, M.D.,

Medical Officer of Dr. Barnardo's Homes and Hospitals.

DR. ROBERT MILNE, whose death on November 8th we regret to announce, was born on a Deeside farm in Aberdeenshire in 1849. He was educated at the Aberdeen Grammar School, and received his medical education at Marischal College, Aberdeen, where he graduated M.B., C.M. in 1874, and M.D. in 1886. For some months he was assistant to Dr. Burns Thomson of Edinburgh, with the idea of going out as a medical missionary to China, but while in Edinburgh he began to have symptoms which were diagnosed as tuberculosis of the hip-joint. He returned to Midmar, Aberdeenshire, where he was confined to bed for a year, and in 1876, while still walking with crutches, he started practising in Midmar. In February, 1880, he accepted an urgent invitation from the late Dr. T. J. Barnardo to come to London to assist in dealing with an outbreak of scarlet fever at the Girls' Village Home, Barking, and in the following May he became medical officer to Dr. Barnardo's Homes. Since that time—for nearly forty years—he remained their chief medical officer; he retired at the end of 1919. During those forty years the Barnardo Homes greatly increased, and now have over 7,000 children under their care. Dr. Milne was beloved by the children and most highly esteemed by every worker with whom he came in contact. His was a many-sided post, especially in the early days, and many a child owes his life and limb to his surgical skill, while to many another death lost its terrors through his Christian and kindly ministry.

Dr. Milne's name will perhaps be best remembered by the medical profession in connexion with his advocacy of the use of injections of eucalyptus oil (or carbolic oil 10 per cent.) in the treatment of scarlet fever. He considered that systematic, thorough injections, in conjunction with the application of 10 per cent. carbolic oil to the throat during the first few days of the fever, modified the severity of the attack and rendered isolation unnecessary. He published articles on the subject in this JOURNAL (October 31st, 1908, p. 1333) and elsewhere. Much success in the treatment of scarlet fever—and also of measles—is stated to have been achieved both in this country and abroad on the lines laid down by Dr. Milne, and his own results were undoubtedly excellent. The general

opinion to-day is, however, that in the present state of our knowledge Dr. Milne's views regarding the absolute efficacy of injection with antiseptic oils in certain infectious diseases must be received with caution.

Dr. Milne's last illness was mercifully short. A gastric ulcer was found at operation on Monday, November 6th; all went well at first, but hæmorrhage from the ulcer commenced, and he sank and died on November 8th. He leaves a widow, five daughters, and three sons; of the latter one is joint medical officer to Dr. Barnardo's Homes, one is surgeon to the London Hospital, and the third is studying medicine.

EDWARD JEPSON, M.D.,

Formerly of Durham.

Dr. Edward Jepson died at Ruislip, Middlesex, after a long illness, on November 13th, aged 73. He was educated at St. Bartholomew's Hospital Medical School, and took the diplomas of M.R.C.S. Eng. and L.S.A. in 1872 and 1874 respectively, and graduated M.D. Durh. in 1889. For forty-two years he practised in Durham and held several appointments. He was honorary surgeon to the County Hospital, medical officer to the Urban District Council, medical officer to the Men and Women's Diocesan Training Colleges. He was Mayor of Durham for two years and a J.P. for the city. He was instrumental in obtaining a higher scale of remuneration for doctors practising in colliery districts. In October, 1905, Dr. Jepson was entertained at dinner by the members of the County of Durham Medical Union and was presented with a roll-top desk and bookcase bearing the following inscription on silver plates: "Presented to Edward Jepson, Esq., M.D., J.P., by the members of the county of Durham in grateful recognition of his arduous and unselfish labour on behalf of the profession in the county and as president of the Union from 1898 to 1905." On the same occasion Mrs. Jepson was presented with a silver tea service. In the amalgamation of the County of Durham Medical Union with the British Medical Association Dr. Jepson took a leading part. He was a member of the Central Ethical Committee of the British Medical Association from 1902 to 1905.

Owing to ill health he left Durham for the south, and after a voyage to India as ship surgeon he was able to take a small practice at Ruislip, which he held until a year before his death. During the war he assisted at Easteote Red Cross Hospital, and also at Victoria Park Hospital, London. He married Jessie Maria, youngest daughter of George Gilliat of Horncastle, who survives him, and one son and four daughters.

ERIC HASTINGS EASTWOOD, M.B., Ch.B. LIVERPOOL,

Lecturer on Pathology, University of Liverpool.

We regret to record the death on November 13th, at Formby, Lancashire, of Dr. E. H. Eastwood, at the early age of 30. Dr. Eastwood entered Liverpool University from Mereham Taylors' School, Crosby, with a Robert Geo Entrance Scholarship. During his academic career he gained the following distinctions: Senior Lyon Jones Scholarship; University Exhibition in Anatomy and Physiology; Torr Gold Medal for Anatomy; and Holt Medal for Physiology. In March, 1916, he graduated M.B., Ch.B. with honours, and distinction in obstetrics and gynaecology.

During his war service he determined to specialize in pathology, and held in succession the appointment of bacteriologist to the Deccan British War Hospital, Poona; to the North Russian Expeditionary Force (Murmansk); and to the Royal Victoria Hospital, Netley. After demobilization he was appointed Pathologist to the Royal Southern Hospital, Liverpool. He held this post for eighteen months, and was then elected Demonstrator of Pathology in the University of Sheffield. Only three weeks before his death he was appointed Lecturer of Pathology in Professor Ernest Glynn's laboratory at the University of Liverpool.

All those with whom Dr. Eastwood worked unite in paying tribute to his ability, his enthusiasm, and his loyal co-operation. The loss of one whose short life was so full of promise is to be deeply mourned.

THOMAS LYLE, M.D.,

Newcastle-upon-Tyne.

AFTER having recorded his vote on November 15th, at mid-day, and having called at the office of the Conservative candidate to intimate the fact, Dr. Lyle, who to all appearances seemed to be in his usual health, made his way homo-

wards. After luncheon he was found by one of his servants lying on the floor dead. It appears that he had not been feeling quite well, for he had consulted at least two of his friends in the profession.

Dr. Lyle was well known and highly esteemed in Newcastle-upon-Tyne, where he had practised for over thirty years. At the time of his death he was 76 years of age. A native of co. Antrim, he studied at Glasgow University, where he graduated M.B., C.M. in 1870 and M.D. in 1872. In the early years of the practice of his profession he held an appointment in Newcastle City Asylum, subsequently in that of the county of Cheshire, and from 1878 to 1900 he was medical superintendent of the Birmingham City Asylum. The experience of lunacy which he thus gained was of great service to him in Newcastle, where his opinion and advice were frequently sought in cases of mental disease. In this department of medicine Dr. Lyle was regarded as a sound and capable adviser. Quiet and unobtrusive in manner, and without malice or jealousy, he made many friends, with whom he remained on intimate terms to the last. Although a keen Conservative he never thrust his political opinions before people. On November 18th his body was laid to rest in Old Jesmond Cemetery. A Presbyterian, the service at the grave was of the simple order of the Church to which he belonged. Many friends, civil and professional, were present at the cemetery.

In the death of Dr. CHARLES EDWIN SOLOMON, after a brief illness, Liverpool has been deprived of one of its well-known practitioners. Dr. Solomon, a native of Cornwall, studied medicine at the Liverpool Royal Infirmary School of Medicine, took the diplomas of L.R.C.P. and L.R.C.S. and L.M.Edin. in 1884, and graduated M.D.Durh. in 1905. He settled down immediately after qualification, and through his diligence gained a considerable practice. He was a member of the Liverpool Division of the British Medical Association and of the Liverpool Medical Institution, whose meetings latterly he attended with regularity. He acted as honorary physician to the G.E.T.S. Women's Temperance Home, where his medical services were greatly valued. Dr. Solomon was essentially a sound practitioner, deeming nothing too trivial that would ensure the comfort of his patient. He was a kind man, and his easy disposition attracted and retained the friendship alike of his professional colleagues and patients. The funeral took place on November 18th, and the number of mourners present showed how highly esteemed and affectionately regarded the late doctor was. Canon Irvine, who conducted the service, pronounced a sincere eulogy on the departed doctor, whom he truly described as a Christian gentleman, a beloved physician, and a trusty friend. Dr. Solomon was a widower, having lost his wife comparatively recently. He leaves behind a grown-up family of two sons and two daughters, to whom we tender our sympathy.

Dr. MYER ARIBA DUTCH died at Brighton on November 10th at the age of 59. He was born in Dublin and educated at the Wesleyan and Erasmus Smith High School. He commenced his medical studies at the Royal College of Surgeons Medical School, where he won several scholarships in medicine and surgery, and qualified in 1882. He practised for several years at Crewe, Cheshire, and, coming to London, established himself in general practice at Walm Lane, Cricklewood, where he made many friends. In 1904 he obtained the M.D. degree of Durham University, and the F.R.C.S.Edin. in 1908; he had taken the D.P.H. of Cambridge in 1891. During the war he was physician to the Bermondsey Military Hospital, and later he took on the duties of officer in command Tudor House and Beech House Military Hospitals, Brondesbury, his services being specially commended. Dr. Dutch was well known in Masonic circles; he was Past-Master of the St. George Lodge, which he founded, and received many Masonic honours. His body was cremated at Golders Green, and his ashes were buried at Willesden Cemetery. He leaves a widow, two sons, and one daughter.

Dr. HENRY PIERCE CUTHBERT died at Pitlochry, Perthshire, on November 6th, aged 59. He was born at Oswestry, the son of the late Rev. George Cuthbert, and on his mother's side was descended from Simon, Lord Lovat, and from Sir Isaac Newton. He was educated at the London Hospital,

and, after taking the M.R.C.S. and L.R.C.P.Lond. in 1889, went into practice at Clun, where he was surgeon to St. Catharine's Hospital and to Trinity Hospital. In 1906 he removed to North Queensferry, Fife, where he was surgeon and agent to the Admiralty and to the coastguard and wireless telegraph station. During the war he took a temporary commission in the R.A.M.C., and served in France and Italy and on troops.

DEPUTY INSPECTOR-GENERAL FRANCIS YEATES TOMS, R.N. (ret.), who died at Hove on November 13th, was probably the senior member of the medical profession in Great Britain, for he had attained the great age of 96. He took the diplomas M.R.C.S. and L.S.A. in 1848, and entered the navy in the following year, attained the rank of fleet surgeon on April 28th, 1872, and retired, with an honorary stop as D.I.G.; on April 1st, 1881. He served as assistant surgeon on H.M.S. *North Star* in 1852-53 in the Arctic Expedition in search of Sir John Franklin, and received the Arctic medal; and in H.M.S. *Sparrow Hawk* in the China war of 1859-60, taking part in the attack on the Chinese forts and gaining the medal. He was awarded a Greenwich Hospital pension on February 6th, 1890.

Universities and Colleges.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

ANNUAL MEETING OF FELLOWS AND MEMBERS.

THE annual meeting of Fellows and Members of the Royal College of Surgeons of England took place on November 16th. Sir Anthony Bowlby (President) took the chair, and placed before the meeting the report of the Council. He indicated the different sections of the report without any particular comment, and called upon Sir John Bland-Sutton to speak of the considerable section dealing with the museum. Sir John Bland-Sutton said that the museum still maintained its pre-eminence. The Council was proud to think that it had been entrusted with what was now known as the Medical War Collection. This numbered altogether some 2,500 specimens, illustrating every phase of injury and disease incidental to the great war. The housing of these specimens had entailed a good deal of structural alteration, but the collection was well worthy of it, not only on account of its size, but because of the interest of the specimens and their careful preservation. Accommodation had also been provided for the Onodi Collection of oto-rhinological specimens, which was now under investigation for the purpose of description and cataloguing. The work would be completed by this time next year.

Dr. Redmond Roche asked the President certain questions with regard to the annual meeting which was summoned last year, and was not held owing to the absence of a quorum. The action of some of the members on that occasion in holding an irregular meeting was the subject of some admixtury remarks in the report. Dr. Roche asked whether it was a fact that members of the Council were in the precincts of the College at the time, but did not make their appearance, as if they had done so a quorum would have been secured; also, whether there was a by-law depriving lady Fellows or Members of the right of voting at the annual meeting. On the last occasion one lady was present, and had it been possible to count her the number would have been the thirty necessary for the quorum.

The President said that the annual meeting was an occasion when Fellows and Members were invited to meet the Council, and as the Council consisted of twenty-four Fellows it was obvious that an attendance of six, apart from the Council, might be sufficient for an annual meeting. This was not desirable, and therefore it was thought well to require the attendance of the thirty apart from members of the Council. Members of the Council were in the precincts of the building on the last occasion. With regard to ladies, the Council was bound by the Act of Parliament under which women were admitted to the College to preclude them from taking part in the management of College affairs.

Dr. Roche then moved a resolution affirming the desirability of admitting Members to direct representation on the Council, and asking for the nomination of at least two Members in general practice. He said that this resolution had been brought forward for twenty years, and had been carried almost invariably by overwhelming majorities, only to be strangled by the Council and buried in the waste-paper basket. No reasons had ever been given for refusing the request of the Members. The government of the College was a mediæval anachronism, and the constitution of the electorate an unblushing usurpation. The result was a Council consisting exclusively of surgical specialists who had no right to speak for general practitioners, who formed the bulk of the members.

The resolution was supported by Dr. F. G. Lloyd, Dr. Arthur Haydon, Dr. Ware, and others, and on being put to the vote was carried by 25 in favour, and two or three against; the members of the Council did not vote.

Dr. M. I. Finucane moved a further resolution requesting the President to make a detailed statement of the reasons, legal and

otherwise, for the refusal to allow representation of Members in general practice. In these days when the provincial universities were making great headway, and new educational systems were being, there was a danger that if the College did not become a more virile institution it might be ignored by the coming medical men. This resolution was supported by Dr. F. W. Collingwood and Dr. Elwin Nash, and agreed to.

The President demurred to the terms of this resolution, which referred to "The Council's refusal to allow representation." That was a misstatement. The Council had power neither to refuse nor to grant. It was strictly limited by its charter, which conveyed no such powers. It was unfortunate also that Members should speak as though there was hostility between themselves and the Fellows; he did not admit that there was any such hostility. In one breath they were told that the status of Members was gravely affected by the action of the Council; in the next, that the status of Members was extremely high. He himself had no hostility to the Members, nor had any member of the Council. Many of the Members were their friends, and many had been their pupils. It was said that this was a matter for which the whole of the Members were pressing. The first resolution spoke of the College as composed of 18,000 persons, of whom 16,000 were engaged in general practice. No indication had ever been given as to how many members there were in the Society of Members; no list of names had ever been published, no figures had been furnished. In the past the Council had consulted the Fellows, who were the electorate, and their opinion on the proposal was adverse. In 1938 the Society of Members asked the opinion of Members of the College, but the result had never been published; it was not known what the result was. Under the circumstances the only way in which the Council could judge of the feeling of the Members was by means of the annual general meeting. There were 18,000 Fellows and Members of the College, and the number of votes cast that day for the main resolution was 26—something like 1.5 per 1,000. He wished to ask the secretary of the Society of Members what was its total membership.

Dr. S. C. Lawrence said that the Society represented the 16,000 members; he had never himself met a Member who justified the Council's action. Two Members thereupon said that the Society of Members did not represent them.

The President, continuing, said that, in the absence of any more definite figures from the Society of Members, the Council had no information as to the feeling of Members on this subject. He was intimately associated during the war with many hundreds of members, and this subject was never raised. It was never raised at all except at the annual meeting, when it was often difficult even to get a quorum. He wished also to point out that the present electorate of Fellows was representative. It was constantly suggested that the Fellows were not in general practice; that was a misstatement. Hundreds of Fellows of the College to his own knowledge were in general practice, and every one of them was eligible for a seat on the Council. He was satisfied that the Council represented every part of the profession. In conclusion he read a statement on the subject which the Council had authorized, giving the reasons against an application for an amended charter. The statement recapitulated what the President had already said: (1) The Council believed the present electorate—that is, the Fellows—to be thoroughly representative; large numbers of the Fellows were in general practice or serving in various appointments under the Government or local authorities. (2) The Council was not prepared to advocate measures which were in direct opposition to the opinions of a large number of the present electorate; on two occasions the Fellows had been invited to vote on an extension of the franchise, and the majority of those voting had been against it. (3) There was no evidence of any widespread demand by the Members for the amendment of the charter, and very few Members came to the annual meeting to support it. If any Members were in doubt as to the legal position he asked them to obtain legal advice, and the Council would give all consideration to any legal opinion. The passing of resolutions at that meeting did not give the Council the necessary powers to do what was demanded.

UNIVERSITY OF OXFORD.

At a congregation held on November 18th the degree of Doctor of Medicine (D.M.) was conferred on A. H. Southam.

The New Schools of Pathology and Pharmacology.

The offer of the trustees of the late Sir William Dunn, referred to in our last issue, was submitted to congregation on November 21st; a delay of a week beyond the date originally fixed having been arranged, in order to allow a fly-sheet of detailed information regarding the proposals to be circulated in the university. The preamble and form of decrees printed below were submitted on Tuesday last to one of the Faculties, and were accepted. The decrees were introduced by the Regius Professor of Medicine (Sir Archibald Garrod), Mr. Arthur Johnson, the President of Magdalen (Sir Herbert Warren), and Professor Poulton.

If and when the offer of Sir William Dunn's trustees has received the consent of the Court of Chancery, the University will be provided with a magnificent "Sir William Dunn School of Pathology," as well as with an excellent School of Pharmacology, in place of the present inadequate provision for the latter subject. Both Professor Dreyer—who is absent in Paris as a British representative at the Serological Congress of the Health Committee of the League of Nations—and Professor Gunn are heartily to be congratulated on the good fortune which has fallen to their

departments from the beneficent action of Sir William Dunn's Trustees.

"Whereas Sir William Dunn's Trustees have offered to provide (a) the sum of £100,000 for the establishment of a School of Pathology subject to the consent of the Court and to the following conditions: (i) that the University provide a site approved by the Trustees, (ii) that the University make permanent provision for the upkeep of a Chair of Pathology and full teaching staff, (iii) that out of the grant a sum of not less than £20,000 be reserved by the University and invested for the provision of a Maintenance Fund for the School of Pathology, and (iv) that the School be known as the 'Sir William Dunn School of Pathology,' and (b) the sum of £50,000 to exist in a Department of Pathology, the University gratefully accepts the offer of Sir William Dunn's Trustees for the purposes aforesaid."

"1. That the offer of Sir William Dunn's Trustees of £100,000 for the establishment of a new School of Pathology, and of £50,000 for the adaptation of the existing School of Pathology as the future School of Pharmacology, subject to the conditions laid down by the Trustees, be gratefully accepted, and that the Curators of the University Chest be authorized to receive the aforesaid sums, and to expend them on the above-named purposes."

"2. That a site of approximately 2.3 acres near to South Parks Road be allocated to the new School of Pathology."

"3. That the warmest thanks of the University be conveyed to Sir William Dunn's Trustees for their most munificent offer."

UNIVERSITY OF CAMBRIDGE.

At a congregation held on November 17th the following medical degrees were conferred:

M.D.—K. R. Aikman, S. D. Kilner.

UNIVERSITY OF LONDON.

At a meeting of the Senate, held on November 15th, the Vice-Chancellor (Mr. H. J. Waring, M.S., F.R.C.S.) being in the chair, the William Julius Mickle Fellowship of £200 was awarded to Mr. P. J. F. Barrington, M.B., M.S., in respect of the work which he has carried out during the past five years on the nervous mechanism of micturition.

The Council for External Students have elected Dr. E. Graham Little as chairman for 1922-23, and Sir Wilmot Herringham has been elected chairman of the Graham Legacy Committee for the same period.

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—G. L. Brocklehurst, G. W. Heckels, *R. Huot Cooke, *J. H. G. Moat, *T. S. North, *W. Winifred A. M. Thompson, *H. L. Wade, *J. H. White, *H. Samson Wright (University Medical), N. D. Hall, J. R. Batten, E. V. Beaumont, J. A. Binning, May H. J. Hakeston, Rosa Job Bradley, R. B. Britton, Lorna P. Brown, E. A. Colclough, Nancy M. Conits, Idris Davies, A. D. D'Arcy, Mary C. Elliot, I. Foldman, Marie L. P. Goetz, Marjorie P. C. Green, Gertrude B. Harre, Hilda M. Haythornthwaite, Margaret Haywood, J. P. Hosford, M. D. Jones, D. J. Jones, W. A. Low, Dora Mason, R. G. Michelmore, Olga V. Naylor, B. S. Nispe, R. J. Parry, F. A. Pickworth, Gladys H. Randall, S. D. Rhind, P. L. Richardson, W. G. Rose, Joan M. Shoss, C. H. St. John, Gladys M. Sados, P. H. Seaton, Olive B. Sharp, H. L. Slater, W. A. M. Smart, Dulcie C. Staveley, Eleanor C. P. Stone, A. J. C. Tugsey, F. H. W. Tzozor, Ion Group I.—Edith I. L. Abbott, Eva D. Cook, S. Crown, G. L. J. M. Laurent, E. A. Levi, Lina M. Sanson, R. O'waino. Group II.—D. A. Blount, Gladys L. Buckley, Helen W. Duncan, Christine P. Francis, F. A. Gaydon, Alice M. F. Goudmann, Kathleen M. D. Harding, Marjorie C. Hawkins, E. G. Housden, G. H. Howells, A. E. Jenks, B. L. Laver, P. R. Lobbane, Mary Michael, Muriel Rawlinson, Olive M. Salmon, A. H. Shelswell, A. I. Silverman, Emma M. Store, H. G. Stormer, R. S. Swindell. Distinction in *Medicine, *Surgery, *Midwifery, *Forensic Medicine.

UNIVERSITY OF EDINBURGH.

The following candidates have been approved at the examinations indicated:

FINAL M.D.—Clinical: T. F. Andrew, H. C. Brayshaw, J. B. Clarke, D. R. Cramb, B. V. Dunn, J. S. Fulton, W. Goldie, Annie C. Greenop, I. S. Hall, T. Harrison, J. D. Ingram, Frans Krone, Ruth M. Monro, J. O. Murray, G. Ogilvie, Helen M. Russell, B. J. Myrie, I. Walker, L. H. Warden. FINAL M.B., B.S.—Forensic Medicine: A. Beveridge, G. P. F. Bowers, P. L. Butler, V. F. T. Chan, J. G. W. R. Dunn, L. M. C. Dunlop, E. G. R. King, R. Levison, Phyllis E. List, A. Morrison, Janet M. Morton, A. J. Rhoda B. V. Robb, R. T. Sharp, R. Smuts, G. H. Thompson, E. J. K. D. M. Wright, D. H. D. Yoncos. Public: F. T. Chan, Elizabeth K. Clark, J. G. B. M. R. Frazer, L. S. G. R. Grant, A. B. Guild, Levison, R. V. Liddell, Melb H. R. Livingstone, R. T. Sharp, D. A. M. Smuts, T. R. Sutherland, Yooll.

EDINBURGH UNIVERSITY COURT.

At the meeting of the Edinburgh University Court on November 13th, with Principal Sir Alfred Ewing in the chair, Sir David Wallace and Dr. Norman Walker, senior lecturers, were

appointed members of the Faculty of Medicine, and Mr. W. J. Stuart was appointed additional examiner in clinical surgery. Intimation was received from the trustees of the late Emeritus Professor Crum Brown of the bequest of a portion of his library to the University. Dr. R. McKenzie Johnston was elected a Curator of Patronage in room of Sir George Berry, who resigned office. The Court appointed Professor Scott Watson and Dr. Charnock Bradley as their representatives on the joint committee on animal breeding.

UNIVERSITY OF LEEDS.

At a meeting of the council on November 20th Dr. A. H. Priestley was appointed lecturer in bacteriology. The following appointments to new lectureships in the School of Medicine were approved: Mr. S. W. Daw (Orthopaedic Surgery), Dr. Veale (Diseases of the Skin), Dr. Vining (Diseases of Children).

VICTORIA UNIVERSITY OF MANCHESTER.

Dr. H. V. WHITE has been appointed honorary assistant lecturer in physiology.

Medical News.

A LECTURE on the present conditions of small-pox will be given by Dr. Richard J. Reece, C.B. (Senior Medical Officer, Ministry of Health), in the Barnes Hall, 1, Wimpole Street, W.1, on Wednesday, November 29th, at 8.30 p.m. The lecture has been specially arranged by the Fellowship of Medicine in view of the present small-pox outbreak and is open to all members of the profession.

THE following members of the medical profession were called to the Bar on November 17th: G. H. Dart, M.D., M.R.C.P., Edin., Medical Officer of Health for Hackney (Lincoln's Inn); W. W. Jameson, M.D., M.R.C.P., Medical Officer of Health for Finchley (Middle Temple); R. St. G. S. Bond, M.B., F.R.C.S., Edin., M.R.C.P., Surgeon Commander R.N., Director of Medical Studies and Professor of Hygiene, Royal Naval College, Greenwich (Gray's Inn).

THE annual reunion dinner of the Prince of Wales's Hospital and North-East London Post-Graduate College was held at Pagan's Restaurant on November 9th. The chairman, Dr. F. G. Crookshank, remarked on the satisfactory number of members present at this the first dinner after the inauguration of the reunion association. The executive committee had deferred bringing forward a definite constitution, but he hoped it would be possible next year to hold a business meeting to consider plans for the future in relation with the College and the North-East London Clinical Society. He asked members to forward suggestions to the honorary secretaries, Dr. Jenkins Oliver, 1, Devonshire Place, W.1, and Mr. S. O. Rashbrook, 1, Priory Terrace, Kew, Surrey.

THE autumn general meeting of the Irish Medical Schools' and Graduates' Association will be held at Pagan's Restaurant, Great Portland Street, on Thursday, November 30th, at 7 p.m., the President, Dr. J. A. Macdonald, LL.D., in the chair. The meeting will be followed at 7.15 p.m. by the autumn dinner, at which the guest of the Association will be Professor Andrew S. Dixon. Tickets for the dinner, 9s. each, may be obtained from Dr. Humphris, 8, West Chapel Street, S.W.

THE Federation of Medical and Allied Services has arranged a conference on hospital finance, to be held at 12, Stratford Place, W., on Thursday next at 3 p.m. The chair will be taken by Lord Islington. Among those who have notified their intention of taking part in the discussion are Viscount Hambleden, Sir Arthur Stanley, Sir Alan Anderson (honorary secretary, King Edward's Hospital Fund), Sir Napier Burnett (Director of Hospital Services to the Joint Council of the Order of St. John and the British Red Cross Society), Dr. Gordon Dill (Brighton), and Mr. E. W. Morris (house governor of the London Hospital).

THE Glasgow University Club, London, will dine at the Trocadero on Friday, December 1st, at 7.30 p.m. Professor W. P. Ker, LL.D., will be in the chair. Any Glasgow University men who have not received cards and who would like to be present are requested to communicate with the Honorary Secretaries, 1, Harley Place, N.W.1.

THE Henry Jacob Bigelow gold medal has been awarded by the Boston Surgical Society to Dr. W. W. Keen for his contributions to the advancement of surgery. The medal was presented at a meeting of the society on October 25th. The presentation speech being made by Dr. Harvey Cushing.

APPLICATIONS for Government grants for scientific investigations must be received at the offices of the Royal Society not later than January 1st next. Printed forms of application can be obtained from the Clerk to the Government Grant Committee, Royal Society, Burlington House, London, W.1.

THE Harben lectures for 1922 before the Royal Institute of Public Health will be delivered at 37, Russell Square, London, W.C.1, by Professor Theodoro Madsen, Director of the Stato Serum Institute, Copenhagen, on December 1st, 4th, and 5th, at 5 p.m. The first lecture will deal with specific and unspecific antitoxin production, the second with antitoxic treatment, and the third with the influence of temperature on antigen and antibodies.

THE next congress of the Royal Sanitary Institute will be held at Hull from July 30th to August 4th, 1923.

THE Paris, Lyons and Mediterranean Railway, 179, Piccadilly, W.1, announces that from December 1st to April 30th next a through coach, comprising lits-salon and first-class seats, will run between Calais and Hyères. This coach will be attached to the through train Calais-Ventimiglia, now running in connexion with the 11 o'clock service from London (Victoria). Luggage registered through from London to Hyères by this service will be examined by the Customs authorities at destination.

THE late Mr. Bourne, of the firm of Bourne and Hollingsworth, Oxford Street, London, has bequeathed £5,000 to the Lowestoft Hospital for the purpose of providing an operating theatre.

THE meeting of the French Association for the Advancement of Science will be held in 1923 at Bordeaux. Professor Sabrazès has been elected president of the Section of Medicine.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL, alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Antiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, Son Bacillus, Dublin; telephone, 5, Rutland Square, Edinburgh telephone, 4361, Central.

QUERIES AND ANSWERS.

PLURIGLANDULAR TABLETS.

"STRATFORD" writes: Recently I have been prescribing pluriglandular tablets (thyroid, pituitary, testis) steadily for several patients. On the principle that the tablets supply a glandular insufficiency, they should be taken continuously perhaps for the rest of life. Are there any dangers in such a course?

PSYCHICAL TRAINING.

DR. CHARLES F. FRANCE (Wigan) writes: "F. J." may find the following work useful—*Amidexterity and Mental Culture*, by Dr. H. Macaughton-Jones (Wm. Heinemann, London).

A STRANGE "WILDFOWL."

DR. GEORGE SMITH (Henley-on-Thames) writes: The strange "wildfowl" described by Dr. Frank G. Layton in your issue of November 18th, p. 1004, must almost certainly have been a tick (*Ixodes*, belonging to the *Acaridae*, one of the families of the *Arachnida*). These ticks are rarely found on man. In thirty-five years of a country practice in Oxfordshire I have only seen one case, and it occurred under almost identical circumstances as those mentioned by Dr. Layton. His patient must have caught it from a sheep, horse, ox, or dog.

WARMING THE GARAGE.

DR. T. S. SHELTON (Chester) writes: Last winter I successfully warmed my 16 x 10 wooden garage by a Perfecta oil-stove standing on the concrete floor a few inches from the radiator. My stove burns for seventeen hours without attention. A simple form of hot-water heating is described in *The Autocar* for November 17th.

STILES.

In reply to the inquiry about stiles (p. 953), Dr. Temple Grey (London) writes: Let "M. P." cut down the carbohydrates and give a liberal dose of sodium bicarbonate before the evening meal, avoiding all local interference (such as pulling out an eyelash, bathing, fomentations, patient's fingers, etc.), and the condition will resolve.

LOSS OF HAIR IN SEBORRHOEA.

"M.B., B.S." writes: Having read the recent discussion on seborrhoea, I should like to inquire whether loss and degeneration of hair can be counteracted by (1) "high frequency" treatment, (2) endocrine administration. In a patient under my care—a woman aged 31 years—local treatment and dieting have been carried out over a considerable period. The somewhat greasy seborrhoea, which seems to date from puberty, is mild in degree, but thinning of the hair is marked and progressive.

INCOME TAX.

"W. B. H." inquires whether the cost of medical books and subscriptions can be deducted in assessing a public salary.

"* Our opinion has been frequently expressed; it is that expenditure incurred in keeping professional knowledge up to standard—not in improving it or in building up a medical library—is analogous to that of maintaining professional instruments in proper condition. The words used in the Act are, however, stringent—incurred wholly, exclusively, and necessarily in the performance of the duties of the office—and where the Commissioners take a different view an appeal would be troublesome and expensive.

"HARD HIT" is in general practice, and has been assessed on the three years' average. Owing to a serious illness he has had to hand over his practice to a neighbouring practitioner, who receives half the fees.

"* Our correspondent is liable to pay tax on the average of the three previous years, and has, we regret to say, no right of relief, in spite of the fact that his professional profits are so drastically reduced.

"H. J. C." bought a Saxon two-seater for £82 10s., and sold it in 1920 for £160, buying a Dodge four-seater for £560. In February, 1921, he bought a Hillman two-seater for £560, but sold it a few months later for £350.

"* If "H. J. C." can show that the car for which he paid £82 10s. would have cost more than £160 when he sold it for that amount, the excess can be charged as an expense of the year 1920. The Hillman car transaction is of course unusual: as the Dodge car was not sold, what really happened was that a further outlay of capital was made, and, in fact, lost. Unfortunately, the Income Tax Acts make no allowance for capital losses, but only for the expense of maintaining the capital sunk in equipment, etc. If "H. J. C." should again buy a second car he could claim to deduct so much of that cost as represented the net cost of replacement of the Hillman car, but the purchase and sale of that car have not, *per se*, given rise to any valid legal claim. On equitable grounds there is a fair claim, but that applies in a somewhat different form to every practitioner who sells a car at a loss when he retires, or for any other reason does not replace it.

"A. R." inquires as to the allowance for various car transactions.

"* (a) Cost of replacement as effected—that is, £225 less £70 = £155. (b) Similar cost—that is, £60 less £20 = £40. (c) Cost of replacement of equipment viewed as a whole would be £225 less £90 = £135. It has to be remembered that the actual out of pocket cost is the maximum amount allowable.

LETTERS, NOTES, ETC

INTRAUTERINE DECAPITATION?

DR. J. D. POLE (Exeter, Devon) writes: On the afternoon of November 6th I was urgently called to attend Mrs. J., aged 22, who had been married two and a half years. She said that she gave birth to a child a year ago, which died at 8 months from "consumptive bowels." Since last July menstruation had been irregular, and she had had menorrhagia for several months (periods three-weekly), but latterly practically amenorrhoea. She said she had been assured by a doctor a month ago that she was not pregnant. Pain in right lower abdomen had occasionally troubled her. On November 5th she had a fall, her lower abdomen striking a piece of furniture. About midday on November 6th she felt a desire to defecate, and a foetus minus the head was ejected, accompanied by a fair amount of haemorrhage. Downbearing pains followed and continued. I estimated the decapitated foetus shown me as four to five months, and there was 8 to 10 inches of cord attached; the neck and end of cord gave appearance of being wrenched or twisted off; the right leg was bruised. A rounded firm mass could be felt through the os and in the anterior fornix fairly high up. No laceration of vaginal walls was observed. The uterus was palpable two finger-breadths above the os, and firm. Ergot was given, and shortly and membranes were passed with

fairly profuse haemorrhage. When seen next day the uterus was no longer palpable; the patient has since felt comfortable, and discharge is slight. I have been puzzled to account for the injury to the foetus. If from the fall, there would surely have been much more evidence of abdominal injury and general shock. If from natural expulsive power, the strength to break through the attachments of foetal head to trunk is greater than what I have hitherto known the uterus to be credited with. The possibility of interference occurred to me, but this was negated.

"* It seems rather unlikely that the abdominal traumatism of the preceding day was the cause of the decapitation of the foetus expelled by Dr. Pole's patient. Since Dr. Pole was not present when the body of the foetus was born it is conceivable that the woman, consciously or unconsciously, may have pulled upon the foetal trunk and so separated it from the head. Such a separation does not require a large amount of force in the case of a four months' foetus; but this possibility could have been judged better if the weight and length had been given. It is, of course, undoubted that injuries of a marked sort when applied to the mother's abdomen in pregnancy, and more especially in the absence of the usual amount of liquor amni, may cause fractures and dislocations in the foetus—Ballantyne in his *Anatomical Pathology*, vol. 1, The Foetus, pp. 48, 393; and vol. II, The Embryo, p. 139, records cases—but commonly there is abnormal fragility of the skeleton in such cases, and these injuries are very different in degree from separation of the head from the body. The "spontaneous amputations in the foetus" described so fully by Sir James Y. Simpson are probably due either to omphalic bands or to some skin lesion; but in one or two of the instances which he reported an abdominal injury to the mother was the alleged cause. The limbs were the amputated parts in Sir James Simpson's cases, not the neck.

APPARENT ABSENCE OF TUMOUR IN CASE OF INTUSSUSCEPTION.

DR. B. S. HOLLICK (Sturminster Newton) writes: In the case of intussusception reported by Drs. Herbert and Norbury (November 11th, p. 922) it is interesting to note the observation that no tumour could be felt through the abdominal wall under the anaesthetic, in the light of a similar case which I saw recently with my partner—Dr. Watts-Silvester—who suspected an intussusception in a baby in whom the symptoms were by no means definite. No tumour could be felt, but as it was difficult to form an accurate diagnosis and the baby very difficult to examine, a little chloroform was administered, after which a distinct tumour could be felt in the right hypochondrium. The child was admitted to a nursing home for laparotomy about two hours afterwards, and on examining the abdomen under complete anaesthesia no tumour could be felt by ordinary palpation, but one became manifest only when examining with one hand behind the right lumbar was then opened and an intussusception ilio-caecum and extending to the transverse reduced. Complete recovery followed. There are two points about this case which induced me to record it: (1) The importance of giving chloroform in a doubtful case of acute abdomen in a small child to facilitate examination; (2) The importance of bimanual examination in addition to the ordinary palpation of the abdominal viscera.

"BAD ARMS" AFTER VACCINATION.

"R. N. M." writes to point out the value of the treatment of bad arms from vaccination by painting the marks and surrounding skin on equal parts of glycerine tincture. Means should otherwise be used.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 31, 33, 34, and 35 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32 and 33. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 199.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE
BRITISH MEDICAL JOURNAL.

	£ s. d.
Six lines and under	0 9 0
7 to 10 lines	0 1 6
11 to 15 lines	1 10 0
16 to 20 lines	3 15 0
21 to 25 lines	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 423, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postal telegrams addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

391.

Syphilis of the Liver.

W. K. HUNTER (*Glasgow Med. Journ.*, October, 1922, p. 225) records two cases of syphilis of the liver with symptoms of abscess formation, showing that such cases may, by presenting fever and rigors, be suggestive of suppuration and be mistaken for abscess, malaria, or typhoid. Case I, a man aged 36, was admitted to hospital complaining of vomiting, jaundice, and ague of several weeks' duration, with a history of occasional malarial attacks during the past eight years. From the intermittent type of the temperature and rigors the case was regarded as possibly malarial, but blood examination was negative, and there was no response to large doses of quinine. Although physical signs pointed to hepatic abscess no pus was obtained on exploratory puncture. Five weeks after admission the Wassermann reaction was taken and was strongly positive; within three days of commencing anti-syphilitic treatment the fever disappeared and convalescence was established. Case II, a man aged 24, complained of severe pain in the upper abdomen with vomiting and slight jaundice. There were tenderness in the left lumbar region and a mass palpable in the region of the gall bladder displacing the heart and liver area upwards. The temperature ranged from 98° to 101.2°, and the leucocyte count varied from 13,700 to 19,000. While exploration was in contemplation a Wassermann test proved strongly positive, and from the institution of anti-syphilitic treatment improvement commenced, the pain and tenderness gradually disappearing, and the epigastric induration lessening with complete ultimate recovery. The positive Wassermann and rapid response to anti-syphilitic treatment in both these cases pointed to the spirochaete of syphilis being the causative factor. In the first case the primary lesion was in the liver, and there may have been an abscess, probably situated far back, though exploration failed to find it. The physical signs in the second case suggested a considerable effusion into the left subphrenic region, probably a gummatous abscess in the left lobe of the liver, directly or indirectly infecting the subphrenic region, and later the left lung, as evidenced by dullness and moist râles at the left base. A further case of syphilis of the liver is reported, simulating gall stones in the severity of the pain, although it was always towards the left rather than the right costal margin. This case improved under salvarsan treatment, and later responded well to increasing doses of potassium iodide.

392. The Treatment of Syphilis with Bismuth Preparations.

B. BLOCK (*Klinische Wochenschrift*, September 16th, 1922, p. 1883) gives his experience of the effects of bismuth preparations in the treatment of syphilis. The value of this drug was shown, clinically and experimentally, by Sazerae and Levaditi in 1921. Most cases have been treated by intramuscular injections of insoluble bismuth preparations. The author considers the best preparation is the combination of bismuth, sodium, and potassium tartrate, known as "Trépol" (especially the recent preparation known as "Trépol indolore"). Intragluteal injections are given twice a week—1 to 2 c.cm. of the 10 per cent. emulsion. For an adult a course of fifteen injections is required. In all three stages of syphilis bismuth injections produce a marked beneficial effect. The author's experience has been similar to that of most French observers. He concludes that we possess in bismuth a remedy which undoubtedly has a very powerful action in destroying the spirochaetes. Clinically and bacteriologically the good effects closely approach those obtained by salvarsan, if they do not equal them, and in this respect it is certainly superior to mercury. But, as regards its influence on the Wassermann reaction, it does not equal salvarsan. Toxic symptoms resembling those caused by mercury may occur. The most frequent are a bismuth line on the gums, resembling the lead line on the gums in lead poisoning, and bismuth stomatitis, which may lead to ulceration. The bismuth stomatitis is a milder affection than mercurial stomatitis. Occasionally slight albuminuria occurs. What place bismuth will take in the therapeutics of syphilis cannot be definitely stated at present, but it is certainly a welcome remedy in cases in which there is intolerance to mercury and salvarsan and in the rare cases in which the mercurial and salvarsan treatment fail. There are no grounds for thinking that bismuth will replace salvarsan, but the author's impression is that bismuth is superior to mercury, and therefore, in the future,

in the conjoint treatment of syphilis the mercurial preparations will be partly or completely supplanted. Recently the author has commenced a combined salvarsan-bismuth treatment, and the results are said to be excellent.

393. The Specific Therapy of Visceral Syphilis.

CESA-BIANCHI (*Archiv. di Patolog. e Clin. Med.*, August, 1922, p. 477) publishes a long article on the treatment of visceral syphilis. After an introduction he describes the differing action of mercurial and arsenobenzolic preparations, and details their advantages and disadvantages and the technique of administration. He then goes on to the symptoms of the various syphilitic visceral lesions, beginning with syphilitic affections of the cardio-vascular apparatus; next he discusses affections of the digestive and respiratory system, the kidney, haemopoietic organs, and endocrine system. He describes various types of syphilitic fever, and in the last two chapters discusses fully syphilis of the nervous system, and adds an extensive bibliography of recent literature on the subject. He says that for most types of visceral syphilis (including syphilis of the nervous system) the associated moreny and arsenobenzol treatment gives the best results—except perhaps in the case of progressive paralysis. Of the mercurial preparations the insoluble salts (especially calomel) are to be preferred. Of the arsenobenzol group the best results are obtained by neo-salvarsan and silver salvarsan, given intravenously in progressive weekly doses. Treatment should be continued with minimum intervals of time according to the general and local state of the patient; lumbar puncture should precede each period of treatment. In the intervals full doses of potassium iodide should be given by the mouth, especially in syphilis of the nervous system.

394. Treatment of Syphilis in the Insane.

T. B. CHRISTIAN (*Amer. Journ. Med. Sci.*, October, 1922, p. 529) states that in the great majority of American state hospitals for the insane, syphilis is not treated. He considers that the opinion of many authorities that latent syphilis is incurable, as far as the production of a permanent negative Wassermann reaction is concerned, does not justify this inaction. He states that in asylums three distinct types of syphilis are found: (1) Cases showing strongly positive Wassermann reaction in the blood and negative in the cerebro-spinal fluid, with no clinical signs of syphilis; these constitute the majority. (2) Cases with positive Wassermann reaction in the blood and negative in the cerebro-spinal fluid, but with clinical signs. (3) Psychosis with syphilis as the etiological factor, such as general paralysis of the insane, tabo paresis and tabes with psychosis. At present he is treating all cases with strongly positive Wassermann reactions, with or without clinical symptoms, including a few cases of general paralysis of the insane. Ninety-five per cent. of his cases belong to the tertiary or latent class with no active lesions or other signs except a positive Wassermann and parietic mental symptoms. The author and his colleagues do not treat cases of general paralysis of the insane expecting a cure but only to ameliorate their symptoms and hold in check the progress of the fatal disease. Only 2 out of 20 cases showed slight mental improvement. The two slightly improved cases showed a lessening of the Wassermann reaction in the blood, but the cerebro-spinal fluid remained strongly positive. Fifteen cases showed no improvement in reaction nor in clinical symptoms. Christian thinks that cases in which improvement has followed intraspinal injections were those in which normal remissions of the disease had occurred. He has discontinued intraspinal therapy in paresis, having had no success, but on the contrary several serious reactions occurred. Intraspinal therapy is, however, he considers, indicated in early selected cases of neuro-syphilis, such as syphilitic meningitis, meningo-encephalitis, or meningo-mycetis. The author gives details of cases in which general paralysis of the insane appeared after prolonged anti-syphilitic treatment and negative blood Wassermann tests, and discusses the period over which anti-syphilitic treatment should be continued in latent syphilis.

395. The Recognition of Mild Hypothyroidism.

J. L. MILLER and B. O. RAULSTON (*Journ. Amer. Med. Assoc.*, October 28th, 1922, p. 1509) assert that every case in which the chief complaint is nervousness should be considered as one of possible hypothyroidism. Increased nervousness was present in all their cases, and was usually manifested by increased irritability and often by moderate insomnia:

the patients were easily disturbed by minor annoyances. Very suggestive was the frequent statement that these symptoms had developed in recent months or years and without apparent cause. Either the patients were conscious of a definite tremor when excited, or tremor could easily be detected in the outstretched hand. Loss of weight was present in only 30 per cent. of this group. There was no definite relation between the loss in weight and the basal metabolic rate. Visible or palpable enlargement of the thyroid was present in 56 of the 61 cases. In a considerable number of instances the patient was not aware of the presence of a goitre. A very definite goitre was rarely present. Exophthalmos, even of a moderate degree, was present in only 10 of the 61 cases. It was pronounced in only 4. In one it was unilateral. One patient with exophthalmos had a normal metabolic rate. In this series of 61 cases only 4 or 5 had been diagnosed previously as definite or probable cases of hyperthyroidism, although all the patients had been examined by one or more medical men. The most frequent diagnosis was nervousness; a few had been considered as organic heart disease; the diagnosis of tuberculosis had been made in a few instances, based on the rapid pulse and loss in weight. X-ray treatment is especially applicable to this type of case. Seventy-four per cent. of this series now consider themselves cured; they are able to pursue their ordinary vocations with, at most, only slight inconvenience. The remainder show varying degrees of improvement, but all received more or less benefit.

395. An Epidemic of Bacillary Dysentery in France.

CAVAILLON and WIBAUX (*Rev. d'Hygiène*, September, 1922, p. 800) record the history of an epidemic of bacillary dysentery which affected the department of the Aisne during the summer of 1921. Starting in April it attacked four persons in the same family, three of whom succumbed. Bacteriological investigation established the etiological part played by *B. dysenteriae* Shiga. Following this preliminary outbreak all was quiet till the end of June, when the disease appeared in a different commune at a considerable distance from the first. Here 98 cases occurred with 11 deaths. Towards the end of the following month another big outbreak, involving 82 cases with 13 deaths, affected a small place in a different department. From July to October several more villages were attacked, some of them showing only a few cases, others minor epidemics. Altogether there were 250 patients attacked, with a total mortality of 16 per cent. Clinically, many of the cases were atypical—so much so in fact that at first the nature of the malady was not recognized. Bacteriologically, the Shiga bacillus seems to have been recovered frequently from the stools, though the number of positive results is not stated. The main substance of the article is concerned with the administrative measures taken to combat the spread of the epidemic. These resolved themselves into (1) a systematic inspection and visitation of the localities involved by sanitary officials, who carried out measures of disinfection; (2) examination of suspected material at a central laboratory; and (3) vaccination and serotherapeutic treatment. Unfortunately the details of those latter modes of action are not very explicit, but it is clear that vaccination was only carried out on a small proportion of the susceptible population. Serum was injected both prophylactically and curatively with apparently beneficial results, though the numbers concerned were too small to permit the drawing of any safe conclusions as to the value of the treatment. The authors are quite convinced that the epidemic was prevented from becoming greater by the vigorous hygienic measures adopted, but they may be reminded how impossible it is to decide on this point in any epidemic, since in every case a natural termination is reached whether efforts are made to control it or not. Knowledge of epidemics is as yet far too small to warrant any self-congratulation on the efficiency of control.

397. Intravenous Injections of Calcium in Congestion of the Lungs.

P. BERNHARD (*Dent. med. Woch.*, October 13th, 1922, p. 1375) has given intravenous injections of 5 to 10 c.cm. of a 10 per cent. solution of calcium chloride at intervals of two to three days in a variety of diseases. The most prompt and dramatic results were obtained in 22 cases of congestion of the lungs. One patient was a man, aged 21, who suddenly developed pneumonia of the left lower lobe, and six days later pneumonia of the right lower lobe. His condition was practically hopeless, and various cardiac stimulants proved useless. Two hours after an injection of calcium chloride tracheal râles ceased to be heard, and in a few days he was afebrile. In two similar cases the injection appeared to save life. In the remaining 19 cases of pulmonary oedema the immediate response was equally satisfactory, but the oedema subsequently returned.

1054 B

SURGERY.

298. Treatment of Malignant Tumours of the Maxillary Sinus.

MM. LEMAITRE, COTTENOT, and SURREL (*Bull. de l'Association française pour l'Étude du Cancer*, July, 1922, p. 457) publish details of the results which they have obtained in 9 cases of malignant tumours of the upper jaw by a combination of paraffin (atypical) resection, x-ray treatment, and radiotherapy. Although the authors have abandoned complete resection of the superior maxilla on the grounds that it is often unnecessary and produces needless mutilation they point out the greater risk, in partial resection, of failing to distinguish between the neoplasm and the surrounding healthy tissue; therefore atypical resections are followed frequently by recurrences. After discussing the various use of x-rays, gamma rays, and radium, and the extended application of prosthetic methods to prevent cicatricial deformities, the authors observe that to-day the problem of treatment of maxillary sinus neoplasms consists in the judicious selection and rational association of the various means of treatment at our disposal. Their 9 cases are grouped as follows: Squamous-celled epithelioma, 5 cases; lymphocytoma, 2 cases; myeloid sarcoma, 1 case; pedunculated sarcoma, 1 case. After using the combined methods of treatment only one case of epithelioma remained apparently cured at the end of three years. The other 4 cases suffered from recurrences, the first patient dying eleven months after the first application of radium. In lymphocytoma, one patient remained apparently cured five months after and the other three years after completion of radiotherapeutic treatment. In the case of myeloid sarcoma "combined" treatment produced violent local reaction, and complete cicatrization was delayed for six months. The pedunculated sarcoma was as large as an orange; it was shelled out, but in less than three months two small recurrences appeared in the region of the operation scar. After four applications of x-rays the tumours disappeared and the patient remained in good health for more than two years. After discussing the various types of tumours of the upper jaw and the details of treatment, the authors conclude that the prognosis of these malignant tumours, very grave before the days of radiotherapy, is to-day much more hopeful. Connective tissue tumours show cures in 100 per cent. of cases, while the more refractory epithelioma show a complete cure only in 1 case out of 5. The recurrence always takes place in the lymph nodes of the face and neck, and never locally. They therefore recommend irradiation of the tributary lymphatic areas, stating that if this procedure is generally adopted it should prove very valuable.

399. Otosclerosis and its Treatment.

A. DELIE (*Le Scalpel*, October 21st, 1922, p. 1005) states that otosclerosis is a familial disease, due to definite changes in the labyrinthine capsule, especially in the bony margin of the fenestra and leading to ankylosis. It is a degeneration; any inflammatory changes are secondary, but they increase the damage. Rarefying osteitis is the last phase of capillary changes in the Haversian canals. The majority of patients are apparently healthy, of arthritic type and placid temperament. The author details many symptoms, and considers that the condition amounts to a trophonosis, a sign of thyroid insufficiency; he advises that these patients should avoid all excesses, and that they should not smoke. Hereditary syphilis should be remembered as a possible complication; if found it must be treated energetically. In other cases thyroid medication and iodine in organic form are indicated. These may be combined, or calcium salts may be given with thyroid tablets to improve the nutrition of bone. During pregnancy and after confinement ovarian preparations should, he suggests, be prescribed in addition to thyroid and calcium preparations. Pilo-carpine prescribed pilocarpine in sudden exacerbations of Pilo-carpine accompanied by labyrinthine symptoms. Pilo-carpine is vagotonic, and may be very beneficial. Belladonna, atropine, and duboisine should be avoided on account of their paralytic effects on the terminations of the pneumogastric. All treatment likely to produce any irritation in the middle or internal ear must be avoided. The patients should avoid all kinds of excitement or emotion and lead a tranquil life. The choice of a profession will be determined by the degree of deafness and deafness by heredity, the disastrous effects produced among the deaf by heredity, the necessity of working in the midst of loud or continuous noise, or of listening constantly to sound (as telephonists do). Artificial drums they are obviously useless when the auditory sense is damaged.

400. Recurrence of Inguinal Hernia.

W. HESSERT (*Surg., Gyn., and Obstet.*, October, 1922, p. 431), in discussing the causes of recurrence following operations for inguinal hernia, finds that the average operator is prone to underate his recurrences. Most surgeons admit from 5 to 10 per cent. of recurrences, all cases considered. Apart from sepsis, failure is due to the inattention of the operator and to not employing that form of repair which is proper for the case at hand. Recurrence is more common in direct hernias due to a deficient conjoint tendon. The cord should be transplanted in this type and a flap of fascia from the rectus sheath used for additional firmness. Most sliding hernias recur, as in these cases excision of the sac cannot be carried out. Castration is justifiable in these cases and the sutures should be placed so that no weak areas are left. Recurrence at the internal ring may be due to faulty ligation of the sac. The most essential feature of every hernia operation is the high ligation of the sac; in children high ligation alone is sufficient to cure the rupture. Where the veins are in excess they should be excised, whilst any fatty tissue which accompanies the cord should be removed, so that the size of the cord may be lessened. Recurrence at the external ring occurs in direct hernia, where a wrong operation has been done, or an indirect hernia during recurrence may traverse the canal and appear at the external ring. No one operation will fit all cases, but the essentials are removal of the sac and closure of the hernial opening by suturing the conjoint tendon to Poupart's ligament. In direct hernia the cord emerges through the aponeurosis as in Halsted's operation. In indirect hernia the cord lies between the two layers of imbricated external oblique fascia.

401. The Conservative Treatment of Pott's Disease

F. LANGENSKIÖLD (*Acta Chirurgica Scandinavica*, July 15th, 1922, p. 51) has treated 237 cases of Pott's disease at a hospital in Helsingfors, and has subsequently traced 148. The total mortality of these cases, which were treated on conservative lines, was 40.5 per cent.; 37 per cent. of these deaths were more or less directly due to the disease of the spine. Only 22, or 16 per cent., were definitely cured, and in 31 per cent. the result of treatment was considered good. The comparative frequency with which the cervical, dorsal, and lumbar regions were affected was in the proportions 16.5, 56.5, and 27 per cent. The prognosis was best for cervical spondylitis, the mortality being only 24 per cent., while good results were achieved in 70 per cent. The prognosis was worst for disease of the dorsal vertebrae, the mortality being 44 per cent., and good results achieved only in 18 per cent. The average stay in hospital of cases with good results was seven months, whereas the average stay for the cases with bad results was only four months. Hence the lesson that hospital treatment should be prolonged and that after-care at home should be carefully controlled. If finances prevent prolonged conservative treatment Albee's bone-grafting operation is indicated.

402. Albee's Operation for Pott's Disease.

H. GÖRRES (*Deut. med. Woch.*, June 30th, 1922, p. 864), who has performed Albee's bone-grafting operation for Pott's disease of the spine in 120 cases, and who is an enthusiastic advocate of this operation, has investigated the subsequent fate of his first 60 patients. Eight could not be traced, two had died within six months of the operation, and in one case the bone graft had become infected and been discharged. Of the remaining 49, 35 were examined by the author, and in all but one case, in which a fistula persisted, complete recovery had been effected. In 22 of these cases more than three years had passed since the operation had been performed, and the results may therefore be said to be permanent. The results in the remaining 14 cases, on which reports were obtained without personal examination by the author, were equally good. In no case had the bone graft interfered with the development or mobility of the spine, and, provided there was no deformity at the time of operation, the contour of the spine remained normal; and when there was deformity at the time of operation there was no subsequent increase in this deformity. The operation did not even interfere with the growth in height of the children operated on, and their spinal mobility was such that they were able to join healthy children in gymnastic exercises. The author stresses in particular the saving of time effected by this operation, which entails a sojourn in bed of only three to four months.

403. Bilateral Pyelography.

GAUDY and STOBBAERTS (*Le Scalpel*, September 9th, 1922, p. 269) say that in radiographing the kidney it is far better to take bilateral pictures, and they describe a simplified process by which this can be done. It consists of two conical needles which can be fitted on to the ureteral sound, connected with a common tube and syringe. The solution used was a 15 per cent. solution of NaI₂, which is painless and gives

good shadows. The presumably sound side is first injected, stopping as soon as any discomfort arises, and then the affected side is injected. Before leaving the patients are given an injection of a small dose of morphine. The authors say no bad results have followed. They give brief details of seven cases, with radiograms. In one case a large double hydronephrosis was shown, 24 c.cm. being injected into the right and 22 c.cm. into the left kidney.

OBSTETRICS AND GYNAECOLOGY.

404. Pre-operative Radiotherapy of Cervical Carcinoma.

A. MAYER (*Zentralbl. f. Gynäk.*, October 7th, 1922, p. 1599) believes that the chief advantage of pre-operative over post-operative radium or x-ray treatment of cervical carcinoma is that the former diminishes the contamination by virulent pathogenic micro-organisms in and around the growth. In radical operations he has found about half of the primary mortality of 20 per cent. to be due to post-operative peritonitis—a complication which is necessarily not preventable by post-operative radiation, but which in a series of 67 cases he reduced to 4.4 per cent. as a sequel to the use of pre-operative radiation in septic cases. His present practice is to operate only on carcinoma showing no evidence of local suppuration; other cases are operated on when, as a consequence of x-ray or radium applications, the local septic conditions have disappeared. In contrast with many observers, Mayer has not found that pre-operative radiation increases to a notable extent the technical difficulty of the hysterectomy by reason of the production of dense scar tissue; the somewhat increased difficulty of dissecting and removing the connective tissue is compensated for, he remarks, by a diminished difficulty in dealing with the pelvic venues. Operating only in the absence of sepsis near the cervix, he has found the percentage of operable cases in his practice to be reduced from 65 to 50; for the cases excluded from radical treatment radiotherapy, however, remains, and as a compensation it is found that radiation renders operable certain cases which, in the first instance, were regarded as unsuitable for hysterectomy. A further advantage of pre-operative radiotherapy is that the cessation of the haemorrhage and the local septic processes permits of the patients being brought to operation at a time when the general condition and powers of resistance have been greatly improved. More probably the disappearance of exudate in the parametria after radiation is due to elimination of sepsis rather than destruction of cancer cells. Patients in whom after radiation all clinical signs of malignant disease disappear show at operation microscopically demonstrable islets of carcinoma cells in the parametrium or adjacent portions of the cervix. The choice of the time (after operation) at which radiation is to be again employed calls for careful judgement.

405. Myomectomy.

ACCORDING to GOULLIQUET (*La Gynéc.*, August, 1922, p. 493), myomectomy is followed by involution of the uterus, the cavity of which returns to normal dimensions at the same time as the menstrual losses become less profuse. True recurrences of myomata are sometimes noted, but, as a rule, after not less than ten years; in one case noted by the author the patient bore two children during the interval between her two operations. Submucous and polypoid myomata are neither amenable to nor suitable for treatment by myomectomy, an operation which Goulliquet finds applicable in about 11 per cent. of myomatous patients. Myomata which are near the exterior or near the fundus of the uterus are specially suitable for myomectomy; unsuitable cases are those in which the removal of numerous interstitial or subperitoneal tumours would leave a distorted and injured "logue utérine." Physiological circumstances should play a part in the presumptive indications for myomectomy—as, for example, in those betrothed, married, or pregnant. The author has seen a mortality of 3 among 104 cases of myomectomy done during twenty-six years, and has been struck by the rarity of post-operative thrombosis or embolus. He has seen eleven instances of ensuing pregnancy. In aged or single patients he prefers to give radium treatment, and in general he advocates hysterectomy in those cases only in which the tumours are exceptionally large, there are coexistent adnexal tumours, or there is suspicion of malignant diseases. COTTE (*Ibid.*, p. 497) records the case of a 1-para, aged 30, who in the third month of pregnancy suffered from dysuria with crises of retention; the myomatous uterus, fixed in the pouch of Douglas, compressed the ureter so much as to render the passage of a sound difficult. A myoma the size of the fist was removed from the posterior uterine wall, and pregnancy continued without interruption.

Lerjicho has had a similar finding in two cases, Condamine in one, and J.-L. Fauro in one. LORIER and DUCHÈNE (Ibid., p. 488) relate the unusual case of a woman who, after having an abortion at the second month at the age of 17, became pregnant twenty-two years later, and suffered during the fourth month of gestation from an attack of acute abdominal pain, pyrexia, and intractable vomiting. At operation the small intestine was found to be acutely kinked by adhesions to an interstitial myoma growing from the right of the fundus uteri; the adhesions having been divided and the myoma (which showed signs of softening and necrosis) enucleated, pregnancy continued almost to term.

406. Intestinal Obstruction from Difficult Labour.

LAMBRETHSEN (*Hospitaltidende*, August 30th, 1922, p. 93) records the case of a 2-para, aged 41, who had aborted four years earlier in the third month. She was admitted to hospital at term. The pelvic measurements were normal, and there was a head presentation with the infant's back to the right. The liquor amnii escaped after labour had lasted fourteen hours. During the following twenty-four hours the head descended considerably, but it could still be felt above the brim of the pelvis. On the seventh day after the escape of the liquor the head could no longer be felt above the brim of the pelvis, and a certain degree of abdominal distension was traced to dilatation of the colon, which felt as thick as an arm, passing from the left iliac fossa across the abdomen. There had been no escape of faeces or flatus, since the previous day. An enema proved futile, and a tube could not be passed more than 6 or 7 cm. up the rectum. Slight attacks of vomiting set in with a rise of pulse. The cervix being fully dilated, ax s-traction forceps were applied, and a live infant weighing 3,800 grams was delivered. There was an immediate and tumultuous escape of flatus, and the colon collapsed after more flatus had been withdrawn by a rectal tube. The vomiting ceased and recovery followed.

407. Detachment of Ovarian Cysts.

ACCORDING to G. COEN (*Annali di Ostetricia e Ginecologia*, September 22nd, 1922, p. 695), detachment of an ovarian cyst, so that its original fixation and nutrition through its pedicle are totally interrupted, is not a very rare event, about eighty cases having been recorded in the literature. The secondary attachments which are required are in many cases oblique, and in about one-fourth of the cases have connected the cyst with the omentum or mesentery, more rarely with the anterior parietal peritoneum, the ileo-caecal regions, the broad ligaments, or other portions of the pelvis. Rokitsansky and Kidd reported a case in which the detached cyst did not appear to have acquired any secondary connexion. In one or two instances it is possible that detachment was due to extreme length of the pedicle, but probably it has nearly always occurred as a sequel to repeated attacks of torsion of the pedicle. The contents of the cyst are not always haemorrhagic. According to Steinmann about one-fourth of cysts which have become detached are dermoids. Coen records the case of a 3 para, aged 53, who three years after the menopause suffered from repeated crises of abdominal pain and vomiting; the ovarian cyst which was removed at laparotomy contained 1.5 litres of fluid, in which much blood and also cholesterol could be recognized. Its wall was thin and the cyst was adherent to the peritoneum of the anterior abdominal wall; no sign of a pedicle or of its former insertion was recognizable.

PATHOLOGY.

408. Group Agglutination.

F. W. ANDREWES (*Journ. of Path. and Bact.*, October, 1922, p. 505) finds that a mass culture of an organism belonging to the *Salmonella* group is not a homogeneous entity, but that there exist side by side bacteria with widely different properties, as shown by agglutination reactions. He describes a method for preparing mono-specific serums by saturating a serum prepared against any member of the *Salmonella* group with all the allied members of this group; by this method stock serum can be stored which reacts specifically with one organism only, the troublesome factor of group agglutination being thus eliminated and more clearly defined results being obtained. Examination of plate colonies of pure cultures of these organisms showed that the colonies fell sharply into two groups: one group reacted well with monospecific serum, but failed to agglutinate with allied group serum; the other agglutinated well with group serum, but only weakly with monospecific serum. The appearance of the colonies of these two different types was identical, and with most of the organisms examined they were in approximately equal numbers. The types did not breed

true, but on cultivation each type changed readily into the other—a change which apparently took place abruptly. A means was found of preparing sufficient suspension of the specific type to use for examination, and such suspensions gave very clear-cut results in the diagnosis of disease, the patient's serum only agglutinating the specific strain of the organism causing the disease. Similarly specific serum can be prepared by immunizing animals with specific types, and such serum enables an organism to be identified with much greater precision and rapidly than when serum is used as prepared in the ordinary way. The facts brought out by this research explain many peculiar phenomena previously observed but hitherto not understood.

409.

Ovarian Inhibition of Conception.

L. HABERLANDT (*Pflüger's Archiv. f. d. ges. Physiologie und Zentralbl. f. Gynäk.*, October 7th, 1922, p. 1627) found evidence, after transplantation into rabbits and guinea-pigs of ovaries from gravid animals of the corresponding species, of a temporary sterilization lasting three months in the former and one month in the latter species. Subsequent examination of the transplanted organs showed the survival of compact groups of large polygonal cells. The author concludes that the inhibition of conception is due to hormones arising from interstitial cells of the ovary of the gravid animal; these hormones cause suspension of ripening or bursting of the follicles. Clinical use of these observations is suggested for the production of temporary sterilization in the human subject for therapeutic purposes.

410. The Action of Antidysenteric Serum on Lysis due to the Bacteriophage of d'Herelle.

P. HAUDUCROY (*C. R. Soc. de Biologie*, October 28th, 1922, p. 966) finds that antidysenteric serum exerts an inhibitory action on the lysis of *B. dysenteriae* Shiga, by d'Herelle's bacteriophage. Thus, if equal quantities of a young culture of the bacillus be placed in a series of tubes, a drop of the corresponding serum be added to each, together with increasing quantities of serum, and incubation carried out, tubes containing small quantities of serum are lysed after three or four hours, but those containing larger quantities are not lysed till after seven or eight hours, while those containing relatively considerable quantities are still opaque after sixteen hours. What is the explanation of this action of the serum? Apparently no effect is exerted on the bacteriophage itself, for if one of the above series of tubes be filtered before lysis has occurred the lytic principle is recovered intact in the filtrate. The serum probably, therefore, acts on the bacillus itself or on some substance secreted by the bacilli which is favoured by the author. During its development produces a soluble substance which is fixed by the serum. The fixing of this substance interferes with lysis. If growth of the organism continues, and more of this soluble principle be produced than can be neutralized by the serum, then lysis will take place. This, however, does not enlighten us as to the nature of the bacteriophage.

411. The Complement Fixation Reaction in Tuberculosis of Domestic Animals.

L. PANISSET and J. VERGE (*Ann. de l'Institut Pasteur*, October, 1922, p. 690) have attempted to ascertain the value of the complement fixation reaction in the diagnosis of tuberculosis amongst cattle. Using Calmette and Massol's technique, with increasing doses of complement in the presence of fixed quantities of antigen, they have studied the serums of 148 tuberculous cows, 63 healthy cows, and 4 dogs. The results obtained were controlled by autopsy of 126 of the tuberculous cows; the other 22 reacted to tuberculin; all the healthy animals were examined clinically and submitted to the tuberculin test. Having taken these confirmatory precautions they find that the complement fixation reaction is positive in 90.5 per cent. of tuberculous cows, while it is negative in 88.8 per cent. of cows clinically free from tuberculosis and not reacting to the tuberculin reaction. Of the four dogs one which was suffering from hypertrophic osteoarthropathy gave a positive reaction, while the other three healthy ones were negative. There is no exact parallelism between the tuberculin test and the fixation test, and the two probably have a different significance; the latter appears to be partly correlated with the extent of the morbid lesions, and possibly with the resistance of the animal, while the tuberculin test is probably unconnected with the richness of antibodies in the serum. They conclude that the complement fixation reaction is of considerable value in diagnosis—especially when positive—but that as it is given frequently by animals infected with other acid-fast bacilli and by those suffering from chronic hypertrophic enteritis, its specificity cannot be considered as absolute.

Comfort in All Weathers.

At £565 the 3-5 std. Torpedo illustrated is undoubtedly the best value offered amongst moderate-powered cars of proved reliability and established reputation.

Fitted with our Allweather-Hood and Side-Curtains, the car is suitable for use in all weathers.

The 12-24 h.p. model is very economical to run (30-35 miles per gallon), whilst its ease of control, silky suspension and sweet running make it the IDEAL CAR FOR A DOCTOR.

12-24 h.p. Chassis and tyres £415
Complete cars from ... £525

A Well-Balanced Food

Analysis shows that the proportions of the various alimentary constituents present in M.O.F. make it a really complete and well-balanced article of diet. It has the further advantage of being a *natural* food, prepared under perfect hygienic conditions, and moderate in price.

For more than forty years M.O.F. has been used with excellent results as a nourishing and palatable food for infants, invalids, and the aged. It is very digestible, though not pre-digested, and it is zanthin free.

SECTION OF MEDICINE.

Professor T. K. MONRO, M.D., F.R.F.P.S., President.

DISCUSSION ON
DEGENERATIVE DISEASES OF THE LIVER.

OPENING PAPER

BY

SIR HUMPHRY ROLLESTON, K.C.B., M.D., D.C.L.,

President of the Royal College of Physicians of London; Emeritus
Physician, St. George's Hospital.

Introduction.

THE change that has taken place in the outlook of clinical medicine, from the era of physical signs to that of functional disorder, is reflected by the subject chosen for this discussion—namely, the degenerative diseases of the liver—for the detection of degeneration of the liver in its early stage largely depends on tests for functional efficiency which are not too elaborate to be carried out in hospital practice. It has thus been shown that functional disturbance, such as may be due to degeneration, may occur in the absence of obvious symptoms, at any rate at the time, and thus information is obtained of diminished resistance in, and damage to, the liver, which may be of value as regards the future treatment of the patient. The experiences of the war in the toxic jaundice of munition workers and the increased attention directed to the jaundice following the treatment of syphilis by salvarsan were discussed in the Pathological Section at the 1920 meeting of the British Medical Association (Miller and Rutherford¹), and the subject of the degenerative diseases of the liver is therefore now ripe for clinical consideration.

The Forms of Hepatic Degeneration.
